THE DISTINCTIVE CHARACTER OF THE TEMPERATURE CURVE OF MEASLES AND OF SCARLET FEVER; AND THE TREATMENT OF HYPERPYREXIA IN THESE DISEASES BY BATHS OF INCREASING TEMPERATURE.*

By HENRY W. BERG, M.D.,
NEW YORK.
VISITING PHYSICIAN TO THE WILLARD PARKER AND RIVERSIDE HOSPITALS; ADJUNCT PHYSICIAN TO MOUNT SINAI HOSPITAL; INSTRUCTOR IN INFECTIOUS DISEASES, COLUMBIA UNIVERSITY.

THE clinical observation of measles and scarlet fever in hospital and private practice has led me to the conclusion that the temperature curve in these two acute infectious diseases is as characteristic and distinctive for each of them as are the respective curves of typhoid, typhus, and smallpox. I am well aware that this is not the view of the vast majority of writers on measles and scarlet fever, and it becomes all the more important that each of us who sees much of these diseases in a systematic way should add his quota of observation to the recognition of the normal course of the temperature curve in these extremely common affections.

The temperature curve of the acute infectious diseases is divisible into three stages: (1) That of accession, including the beginning and rise of the temperature to its maximum; (2) the fastigium or stage during which the temperature continues at its height before the positive decline has set in, which forms (3) the stage of defervescence. The first stage may be an acute steep rise to a high temperature in the course of a few hours, or a gradual rise, continuing for days before the fastigium or period of maintenance is attained. The second stage, or fastigium, also varies in duration in different diseases. In some the temperature is maintained for some days, in others the fastigium is scarcely attained before the third stage of the temperature, or that of defervescence, begins. Of the third stage, there are two types. When it declines rapidly, as in pneumonia, the temperature is said to resolve by crisis; when it declines gradually by a slow diurnal descending staircase movement, the resolution is by lysis.

Before discussing the temperature curve of the two diseases to which these observations are limited, I wish to object to the customary description of the symptoms of measles and scarlet fever under the head of the stage of invasion or prodromal stage, the stage of eruption, and the stage of desquamation. The stage of invasion or prodromal stage corresponds with the appearance of the enanthematic eruption upon the mucous membranes, those of the conjunctiva, the nasal fossæ, buccal cavity and inside of the lips and cheeks in measles, and the pharynx, tonsils, and tongue in scarlet fever. This stage is as much a part of the eruptive stage as is the exanthema itself. The so-called prodromal temperature is the temperature of the enanthematic stage of the eruption. The conception of the desquamative stage as synonymous with that of defervescence is also faulty, in that it would give the impression that desquamation begins with defervescence or disappearance of the eruption, which is rarely true even in measles, and is never true in scarlet fever. Every one who sees much of the latter disease knows that, as far as the skin lesion of this disease is concerned, there is in a large proportion of cases a period of three to eight days or more after the eruption has entirely disappeared and the skin has become normal to the eye and touch before desquamation begins. During this period the most expert clinician could not, in many cases, affirm from the presence of any positive symptoms that the patient had suffered from scarlet fever, and when the history points to that disease he awaits the appearance of the characteristic desquamation. While this is not true of measles, in which the skin does not return to its normal color or appearance until after desquamation is completed, yet even here the fading of the characteristic eruption is not, as a rule, immediately followed by desquamation, but there is generally a period of some days before desquamation sets in. If these diseases must be described clinically under the head of stages, it would be more logical and true to write of them as (1) the eruptive stage, including the enanthematic and exanthematic periods; (2) the stage of defervescence; (3) the stage of desquamation.

The pyrexia of measles and scarlet fever, due to the respective specific infectious cause of these diseases occurs during the eruptive stage as thus defined and the stage of defervescence. By that I do not mean that the rise and fall of temperature that occurs during these stages of all cases of measles and scarlet fever is due to the specific virus of these diseases, emphatically not; for very many suffer during the earliest as well as the latest stage from a variety of complications and mixed infections, each of which causes modifications and deviations from the temperature curves characteristic of measles and scarlet fever when these diseases are uncomplicated. What is meant is that the characteristic temperature curve of measles as well as the characteristic temperature curve of scarlet fever covers the stage of eruption and the stage of defervescence.

Let me then describe the characteristic temperature curve of an uncomplicated case of measles in which there is pyrexia. During the enanthematic period of the eruptive stage the pyrexia is moderate; it rises toward night, it declines about a degree toward morning. It lasts for from two to five days. There is a slight increment of pyrexia every evening as compared with that of the evening before. There is, however, a sharp decline, sometimes to within a degree of the normal, on the morning of the day when the skin eruption (face) is to appear. Synchronous with the appearance of the exanthema, the pyrexia becomes greater and the temperature rises rapidly, generally to a higher point than any

*Read before the New York Academy of Medicine, May 19, 1904.

reached during the enanthematic period of the eruptive stage. On the first day of the skin eruption, with the appearance of the exanthema on the face, the temperature is apt to be a degree higher than the highest figure of the enanthematic stage. From this figure there is a decline of about a degree

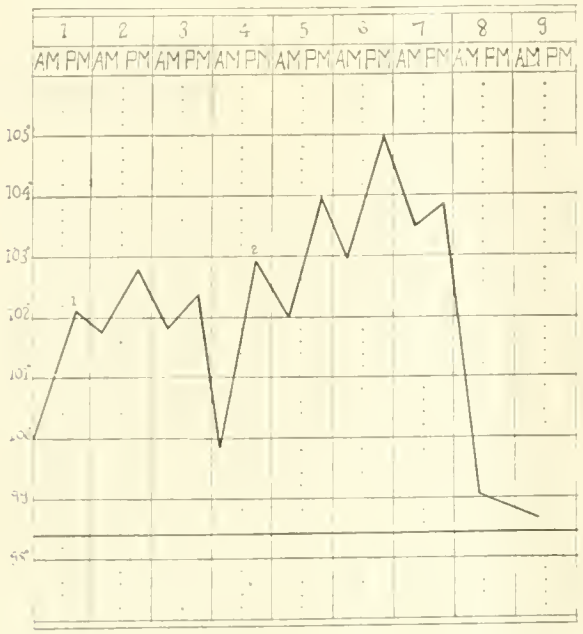

Chart 1. Schematic Measles; 1, enanthema, 2, exanthema.

by the following morning. During this second day the eruption covers the neck, chest, arms, and shoulders, and toward night the pyrexia is about a degree higher than that of the evening before; there is a slight decline toward next morning. On that day the eruption covers the abdomen, back, and thighs, and the temperature rises by evening a degree or a degree and a half higher than the evening preceding. This is the maximum height during the whole course of the essential temperature curve of the disease. It again falls

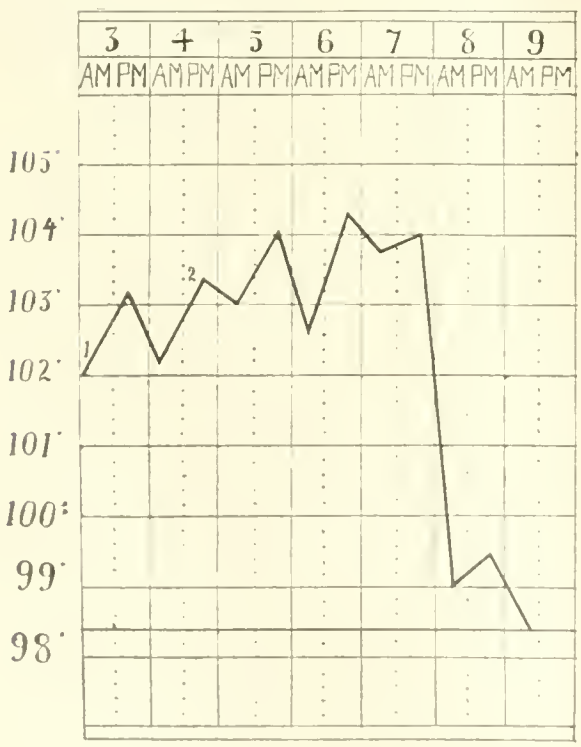

Chart 2. Measles. Jos. E.; 1, enanthema, 2, exanthema

one or two degrees by morning of the next day. During this day the eruption becomes complete, covering the legs and dorsum of the feet. The temperature again rises toward night, but not as high as the night before. During the night and following morning there is a decline or defervescence, abrupt and sharp, either down to the normal or almost normal, within twelve to twenty-four hours, or the abrupt decline may be interrupted at about midway by a slight evening rise and then an abrupt

decline to the normal by the following morning. This is schematically shown in chart 1 and in chart 2, the latter a complete uncomplicated measles curve from a case in private practice. If I were asked to indicate the most characteristic phe-

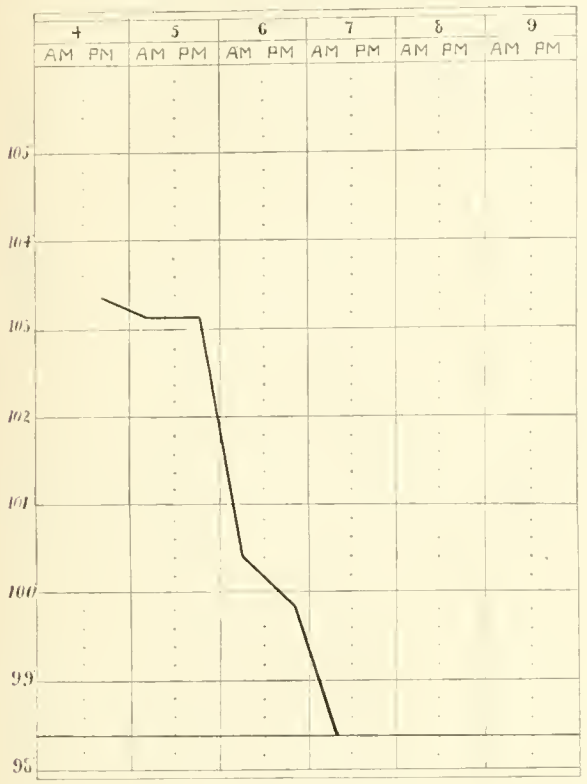

Chart 5. Measles. Annie G.

nomenon in the typical measles tempera ture curve I should say that it is this tendency to resolution or defervescence of the pyrexia by crisis. In this respect it differs positively and absolutely from the temperature curve of scarlet fever, in which, as I shall presently show, the resolution of the pyrexia takes place by lysis.

Frequently in severe cases of uncomplicated measles the writer has been able to predict that the temperature would fall to the normal on a certain given day, although on the day previous, at the time of the statement, the temperature was still at a very high and even alarming figure. This prognosis rested upon the absence of any complication in that particular case, and my absolute reliance on the positive fact that the pyrexia of uncomplicated measles always undergoes a resolution by crisis, as indicated above. The temperature curves taken from the histories of normal uncomplicated measles cases demonstrate graphically what I have attempted to describe at length. (Charts 2, 3, 4, 5, and 10.) All but chart 2 are temperature curves from cases in the Riverside Hospital.

Scarlet fever, when uncomplicated, has a much simpler temperature curve than measles. Nevertheless this curve is characteristic of this disease During the development of the enanthema synchronous with the initial vomiting and sore throat the temperature reaches a very high degree, frequently the highest point of the temperature curve. The enanthematic eruption is very rapidly followed by the exanthema, sometimes within six or eight hours, generally within one or at most two days. During this time the temperature is maintained at its height, suffering only the usual decline of a degree or a degree and a half toward morning, to rise again at night. If the skin eruption is delayed a slight drop in temperature precedes it. (Chart 7, from a case in private practice.) With the appearance of the exanthema the temperature is maintained at its height for three or four days more, while the eruption covers the body. The first slight decline is noticed when the eruption has reached the lower part of the legs and dorsum of feet, about the third or fourth day. This decline is slight, not more than two degrees, followed by a slight rise at night, but not as high as the temperature of the previous night, next morning again to decline to a degree or a degree and a half lower than the morning before, and so on, the temperature curve descending by steps very much after the manner of the typhoid curve until the normal is reached after five to eight days. In this disease the defervescence of the pyrexia is by lysis. This curve is schematically shown in chart 6, while chart 7 shows a curve from a case of uncomplicated scarlet fever observed from its very beginning to its end.

The temperature curve of measles as compared with that of scarlet fever shows the following points of difference: In measles the accession of the fever is gradual (shown in charts 2, 8, and 9), the fastigium limited (charts 1 and 2), and the defervescence by crisis (charts 1, 2, 3, 4, and 5). In scarlet fever the accession is acute (charts 6 and 7) and sudden, the fastigium lasts through almost the whole of the eruptive stage (charts 6 and 7), and the defervescence is by lysis (charts 6, 7, 11, 12,

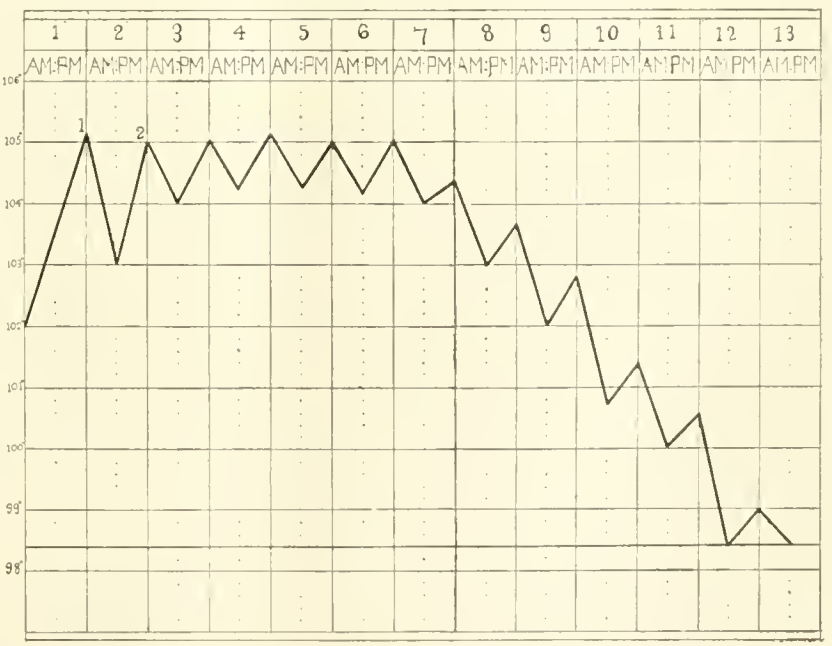

Chart 6. Schematic Scarlet Fever; 1, enanthema; 2, exanthema.

13, 14, 15, and 16).* I have spoken only of the uncomplicated measles and scarlet fever temperature curve, carefully abstaining from giving any abso-

(*Charts 10 to 16 are from cases in the Riverside Hospital, scarlet-fever service.)

lute temperature figures. For the general trend of a temperature curve that is distinctive and characteristic of a disease must be true, whether the pyrexia be a severe one with high temperature, or mild with very low temperature.

There are said to be also cases of measles and scarlet fever which run their course without any temperature. I have never seen such a case in hospital or private practice. I have frequently seen cases in which the fever has been very slight, but recognizable by rectal thermometric observations. I have certainly heard from mothers whose children showed by a characteristic desquamation and other symptoms that scarlatina had run its course in the little patient, and that there had been no fever accompanying the rash, but such statements resting solely upon nonprofessional observation and frequently lack of observation can hardly be taken as the basis for clinical data.

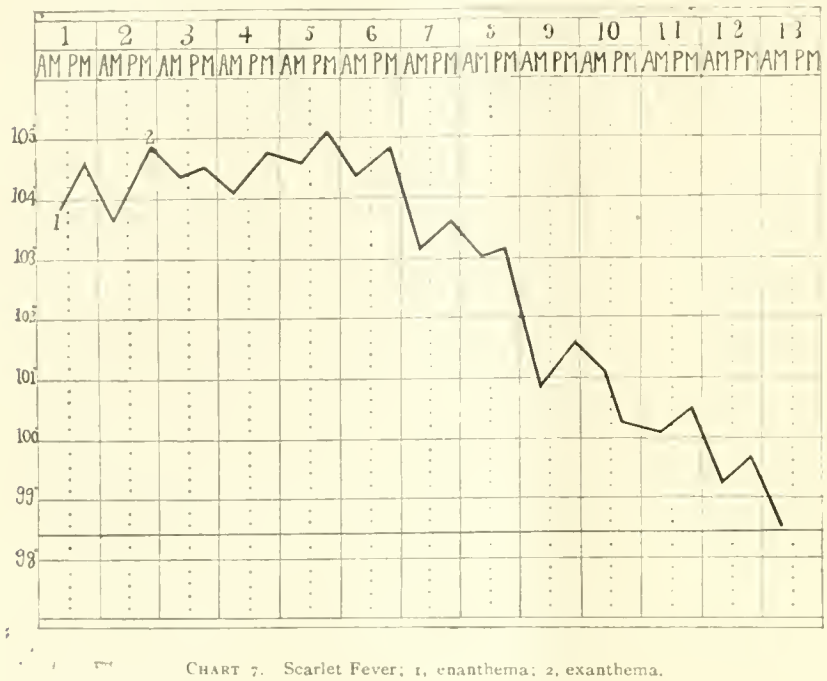

CHART 7. Scarlet Fever; 1, enanthema; 2, exanthema.

Of great importance is the fact that eminent authorities differ as to whether the temperature curves of measles and of scarlet fever are respectively distinctive of these diseases. Scarcely any two works on medicine agree as to the temperature curves of either measles or scarlet fever. Thus Wunderlich (Eigenwärme in Krankheiten, 1870), whose thermometric studies are classical, considers the measles curve absolutely distinctive, and that of scarlet fever also, under certain limitations. The curve for scarlet fever, which I have found in my experience differs from that of Wunderlich in many particulars, and my impression does not confirm the views of Wunderlich with regard to the measles curve in many respects, but the critical defervescence in measles and the defervescence by lysis in scarlet fever Wunderlich emphatically recognizes. Indeed, this shrewd observer makes this broad statement:

"The course of the temperature must be individual and characteristic in each separate infectious disease; each must present its typical curve, and if we fail to recognize it, the fault certainly lies with us." (Über einige Verhaltnisse des Fieberverlaufes bei Masern, *Archiv der Heilkunde*, 1863, p. 332.)

Just as we commonly accept as characteristic of smallpox, its well-known, peculiar temperature curve, and as characteristic of typhoid and typhus fever, the recognized curve of the pyrexia in these diseases respectively; to this extent at least, is the fever curve in measles and scarlet fever distinctive. The objectors to this view, prominent among whom are Thomas and also von Jurgensen, seem to expect more uniformity in the course of the fever of measles and scarlet fever as a *sine quá non*, for considering them distinctive, than they do from the curve of the fever in typhoid and typhus, which they agree are eminently distinctive. And yet variations from the typical fever course in measles and scarlet fever can be accounted for more easily and are far less numerous than the variations from the typical course in typhus and typhoid. One important reason why physicians do not recognize how typical are the fever curves of measles and scarlet fever, lies in the fact that pyrexia in these diseases, when uncomplicated, is much shorter in duration than that of typhoid and typhus. Then, too, complications of an inflammatory nature frequently mask the characteristic curve in scarlet fever and measles. Especially is this true at the period of defervescence, when, in an uncomplicated case, the fever would defervesce by crisis or pseudocrisis in measles, and by lysis in scarlet fever. Then, too, measles and scarlet fever can be observed in numbers sufficient to enable one to make deductions as to the fever curve only in infectious disease hospitals which are few in number;

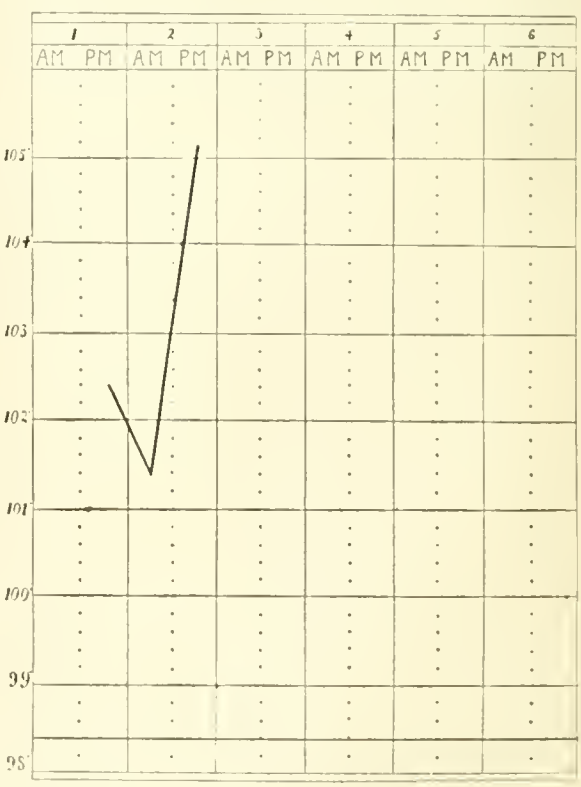

CHART 8. Measles, end of enanthema and beginning of exanthema. Louis L.

while of typhoid every general hospital furnishes sufficient material. Even in infectious-disease hospitals the cases come in too late for frequent observation of the first two, or even three, days of the curve. I have been compelled to study the behavior

of the fever curve in the first days of the disease, in my private practice.

I present some curves of the earlier days of two measles cases which I owe to the courtesy of Dr. M. Gershel, Physician to the Hebrew Sheltering Guardian Society (charts 8 and 9).

I have sought to explain the fever curve of measles and of scarlet fever. In both of these dis-

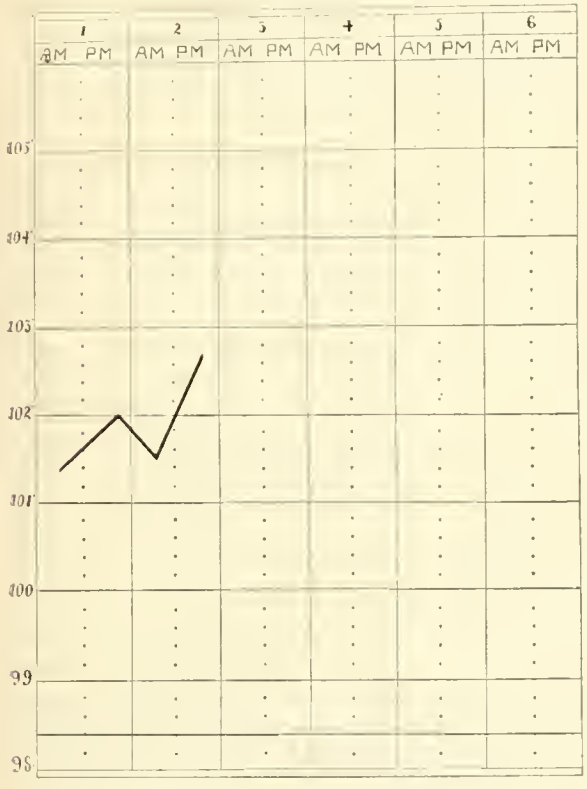

Chart 9. Measles, showing curve of exanthematic stage. Clara C.

eases the pyrexia is the combined result of the influence of the pathogenic germ and its toxins upon the various biological and chemical processes going on in the blood and tissues of the body, which are heat producing, as one factor, together with the rise in temperature produced by the inflammatory process going on in the mucous membranes and skin, to which the enanthema and exanthema are due, as another factor. I believe the latter factor to be dependent upon the former, for, in my opinion, the eruption in the acute exanthemata is simply a conservative inflammatory manifestation on the skin and mucous membranes due to their activity in helping to excrete from the system the toxic materials present in the blood and tissues. The influence of the toxæmic element in the production of the pyrexia is less in measles than it is in scarlet fever. On the other hand, the cutaneous inflammatory process involved in the eruption of measles has a more important influence on the pyrexia curve than the skin lesion of scarlet fever has on the temperature curve of that disease.

Keeping these two causative factors of the pyrexia in view, let us consider in the light of them the measles curve. The first portion of the pyrexia curve, during the enanthema is moderate even in cases of some severity, about 103° F., and is due to the catarrhal inflammation of the mucous membranes of the mouth, nose and eyes, plus the effect of the activities of the toxic agents. The slight drop in the fever before the appearance of the exanthema is due to the fact that the acme of the inflammation in these mucous membranes has been passed and that causative element in the pyrexia is therefore diminished. On a similar basis can be explained the rise in temperature with the appearance of the eruption on the face; the further rise on the following day as the eruption covers the chest; the rise to the maximum of the curve as the eruption spreads over the largest area on the third day of the exanthema, when the eruption covers the abdomen, trunk, and thighs; the decline as these surfaces are covered, followed by a rise, to a lower plane, however, with the appearance of the rash on the lower legs and dorsum of the feet, owing to the fact that the cutaneous surface involved is far less in extent than that covered on the day previous; and, finally, the rapid decline by crisis to the normal, due to the fact that the inflammatory disturbance in the cutaneous surface has run its course. All of these changes can be explained by taking these two causative factors of the pyrexia into consideration.

Nor is it essential to believe that with the disappearance of the fever, the toxic element should have been entirely extruded, provided a sufficiently large share of it has been neutralized and excreted by the skin and mucous membranes, so that it is no longer necessary for the body cells to continue the excess of chemical and biological activities of which the pyrexia was a manifestation and which preserved the cells in their contest against the activities and products of the bacteria of which the infection consists.

In scarlet fever the toxic agent plays a more important rôle in the production of the pyrexia than does the inflammation of the skin or mucous membranes; nevertheless, the latter, as in measles, has its effect, as is well shown in cases of scarlet fever in which the enanthema is not followed within a few hours by the exanthema on the shoulders and face

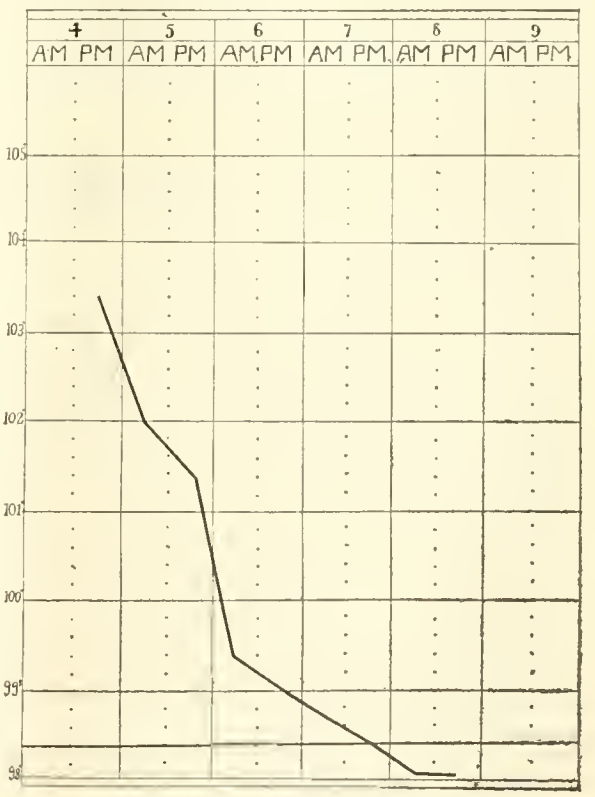

Chart 10. Measles, Defervescence. John H.

as is usual, but where such exanthema is delayed for two or more days, as is the case in the curve of normal scarlet fever shown in chart 7. In such cases there is a drop in the high temperature after the enanthema has appeared and before the exanthema appears (charts 6 and 7). But when the eruption becomes manifest the temperature rises to the high

point which it had attained with the initial tonsillitis and pharyngitis and vomiting, and the fastigium lasts, as already shown, with a slight increase on the third day of the eruption, for reasons similar to those spoken of under measles, but otherwise not showing the daily increment in the fever due to the involvement of additional skin areas in the eruption. For, in this disease, as I have already said, the local skin lesion plays a much less important part in the production of the pyrexia than does the toxæmia. The whole clinical picture of scarlet fever supports this view; the initial toxic vomiting, the rapid pulse and the frequency of toxic complications. This toxic element is sufficient to keep up in the body cells their fever-producing activities even after the eruption has reached its height and is subsiding. However, gradually the toxic agents are overcome, and this slowness is pictured in the gradual resolution of the fever by lysis; the temperature, while declining daily, does not reach the normal until four days to a week or more after the eruption has run its course. (Charts 6 and 7, and other defervescent scarlet fever temperature curves.)

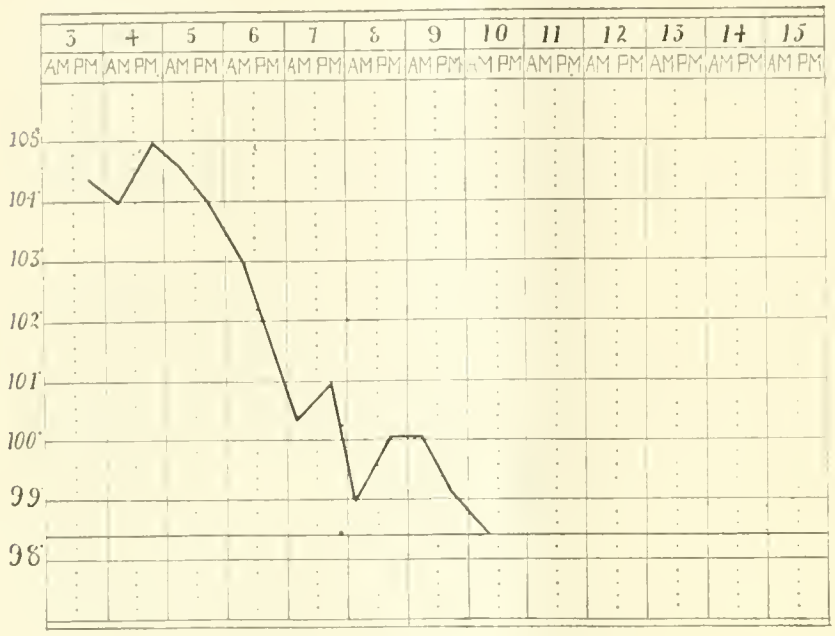

Chart 11. Scarlet Fever, Defervescence. John McK.

With this view of the temperature curve and its pathogenesis, it is possible by careful examinations of the patient from day to day to account for any positive departure from the typical fever curve in those suffering from these two diseases. Nor is it surprising that slight variations occur even when there are not decided complications. These two eruptive fevers, for the most part, affect children in whom even the normal temperature curve of the body in health is readily disturbed by comparatively unimportant factors, and yet so typical are the respective fever curves in these two diseases that variations in uncomplicated cases will admit of explanation on careful study of each case, and will serve only to prove the rule. Such reliance can one place upon the typical character of the curve, in my experience, that if a positive variation from the usual curve is seen, a complication must be sought for and will generally be found. Thus, if the critical drop in the temperature curve of a measles case in the defervescence of the fever has taken place, and a rise in temperature follows, it can be positively affirmed that there is a complication, such as pneumonia, otitis media, meningitis, etc., which a careful examination of the patient will reveal. If the critical resolution does not occur, but defervescence is only partial, the fever continuing as the eruption is fading, a complication, as a cause for the continued fever, will be found. Furthermore, if the course of the fever is not in a general way in accordance with the typical curve throughout the whole of the eruptive stage, and a careful examination reveals no complication, I have generally found that the critical defervescence will not occur, and gradually the concealed complication shows itself. In other words, an irregular curve will put the careful clinician upon his metal to discover the complication which causes the irregularity. In one of my cases an inflammatory rheumatism, involving at first only the vertebral articulations but later on other joints, gave rise to a septic temperature curve in a case of measles with a typical enanthematic and exanthematic eruption. Even the presence of very high pyrexia in cases with a normal measles temperature curve enables him who is familiar with the measles curve to predict a critical drop at the proper time, especially if a careful physical examination has failed to reveal any complicating condition.

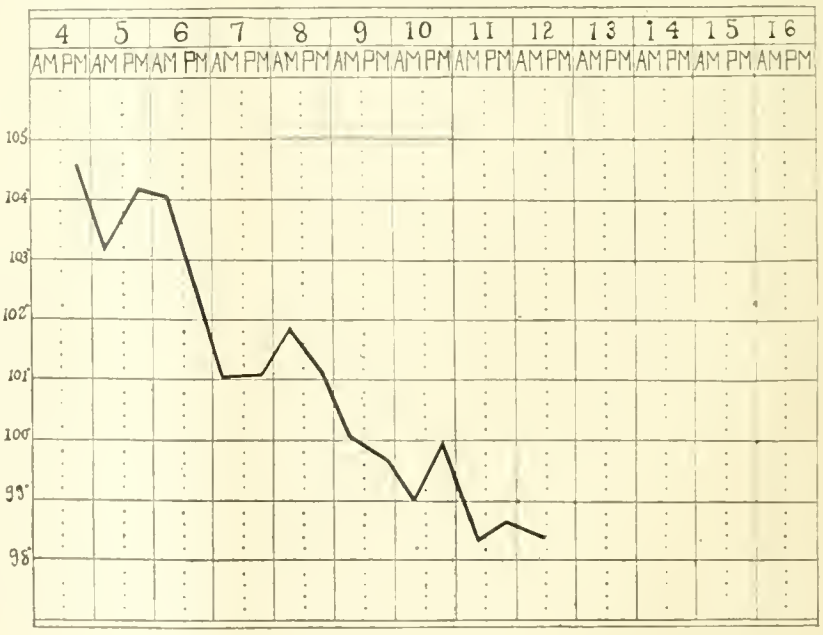

Chart 12. Scarlet Fever, Defervescence. Mary B.

In scarlet fever a knowledge of the normal curve will enable the physician and the patient's friends

to look with equanimity upon rather high temperatures during the fastigium, provided no complications are found. When, however, in the stage of defervescence resolution by lysis has begun, and after a day or two is interrupted by a renewed rise to the higher figures of the fastigium, then a complication must be sought for and found, for the scarlatinal virus uncomplicated never causes a renewed rise of temperature in the stage of defervescence when lysis is in progress.

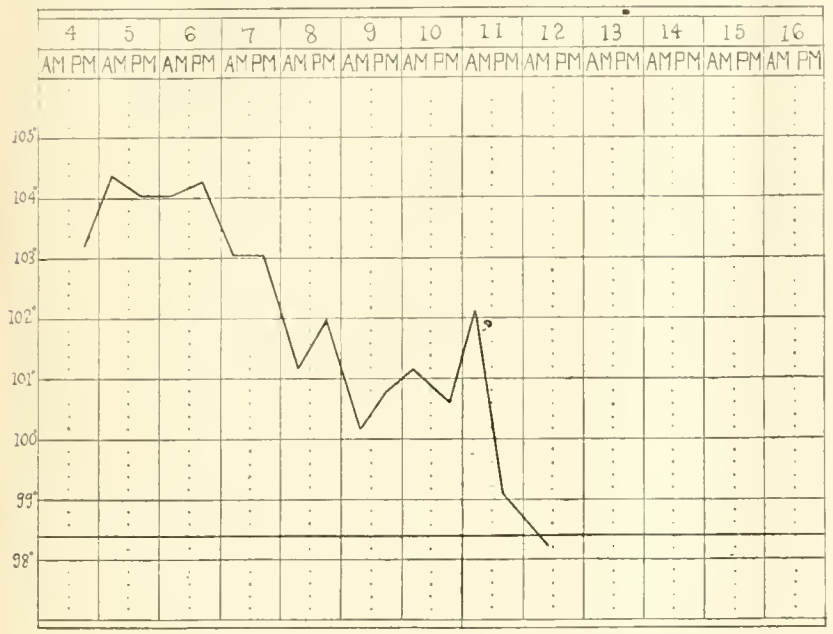

Chart 13. Scarlet Fever. Arthur M.

A knowledge of the normal temperature curve of scarlet fever will enable us to estimate at its true value any serum therapy proposed as a specific for the disease. For a specific serum treatment tried even in large numbers of cases may result, owing to the severity of the cases upon which it has been tried, in a larger death rate than that shown in the total mortuary statistics of a city where the death rate is based on all the cases of scarlet fever which have been reported, both severe and mild. But if the serum recommended really antagonizes the toxic elements of the disease, it must necessarily cut short the fever which is also dependent upon these toxic agencies. I should expect such specific serum injections, whether of the antitoxic or antibacterial type, to produce a prompt shortening in the duration of the fever of the fastigium and a defervescence, of the critical type, within twelve to twenty-four hours after the injection. I have accordingly attached no importance to the antistreptococcus serum therapy, owing to the fact that in the cases in which I have observed the Marmorek and Moser serum used, I have failed to see such or like influences upon the typical temperature curve of scarlet fever, as a sequence of these serum injections. A recovery after the use of the serum means little, for scarlet fever is cured without serum therapy. A change in the curve of the defervescence from lysis to crisis would mean very much. The successful antiserum, when discovered, I am sure, will show as one of the important clinical changes, a shortening of the fastigium of the fever curve and a resolution of the fever by critical drop and not by lysis.

In the course of my remarks I have purposely avoided any reference to absolute high or low temperatures in measles and scarlet fever, the object of this study being the development and recognition of the typical character of the uncomplicated temperature curve from day to day, irrespective of its absolute height or lowness. I may be permitted, however, to speak of the practical and important question of the treatment of hyperpyrexia in these two diseases. I think we may assume, for the purposes of this paper, that occasionally in measles and scarlet fever even when uncomplicated, the temperature, owing to its extraordinary height, may require therapeutic attention. This, notwithstanding the fact that from what has been said, our knowledge of the character of the curve enables us to predict its duration and probable extent as long as no complicating conditions occur. All the more does the temperature, when excessive, require attention in those cases in which complications exist; for not only is the temperature in some of these cases apt to rise to much higher levels, but owing to the uncertainty of its duration we must avoid as far as possible the evil effects of hyperpyrexia which the patient may have to endure for some time. The usual methods for reducing temperature in infectious eruptive fevers, employed also in measles and scarlet fever, are cold or cool baths, like the Brand baths, used in typhoid, cold or cool sponge baths, cold pack, and antipyretic drugs. The last, we may dismiss with an interdiction. I do not know of any of the acute infectious diseases in which these drugs

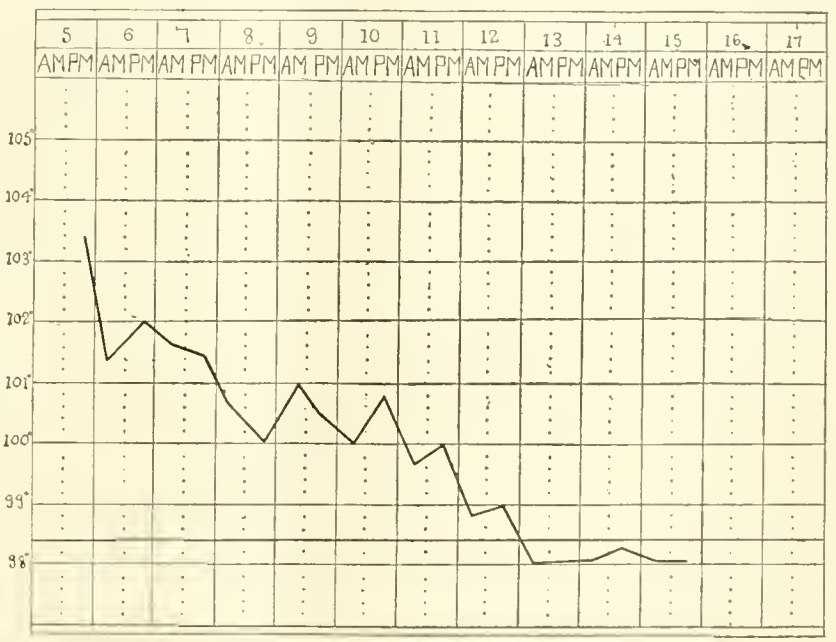

Chart 14. Scarlet Fever, Defervescence. Rose G.

are warranted for the reduction of hyperpyrexia. The reasons for this are for the most part well known and we need not enter upon them here. As far as the use of the other three methods is concerned, baths, sponge baths, and the cold pack, one fact is true with reference to all three of these methods of reducing hyperpyrexia when applied to measles and scarlet fever, and that is that no such reduction of temperature, either in amplitude or in duration, as is obtained from these methods in the high temperatures of other diseases, such as typhoid or pneumonia, takes place from their use in the pyrexia of measles and scarlet fever. This is easily accounted for. In both of these eruptive diseases, cold, whether in the shape of baths, sponging or packs, has a different effect upon the skin, which is the seat of an exanthema, from that which it has in diseases in which the skin is in a normal condition. The subcutaneous swelling and infiltration which is a part of the eruption causes pressure upon the cutaneous capillaries and their nerves. These capillaries do not undergo the primary contraction under the influence of cold which occurs when cold is applied to healthy skin, nor does the secondary dilatation which follows the primary instantaneous contraction where the skin is normal, occur in skin which is the seat of a measles or scarlatinal eruption. There is, therefore, not that interchange of cooled blood from the periphery and warm blood from the center which is so necessary a condition to the reduction of temperature by cold baths or pack. On the contrary, I have seen these agents when applied to a brilliant scarlatina cause the red rash to become violet and almost hemorrhagic and spotted in character, owing to stasis of the cutaneous circulation.

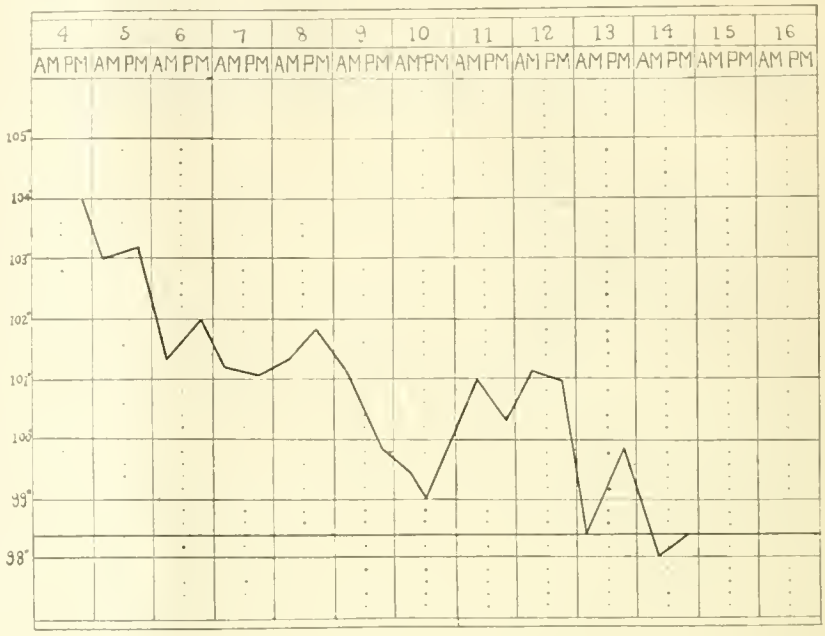

Chart 15. Scarlet Fever, Defervescence. Sylvester M.

For the same reason cold baths and cold packs in measles and scarlet fever inhibit perspiration both primarily and secondarily. I have referred above to the importance of the sweat glands in aiding the skin to excrete from the body the toxic materials which are the essence of the disease in measles and scarlet fever. I even believe that the eruption itself is the conservative manifestation of the eliminative activity on the port of the skin; so that any method of reducing temperature which inhibits the eliminative and excretory functions of the skin defeats the most logical indication for therapy that we have in the acute infectious eruptive diseases. A gentle perspiration during the course of the eruptive stage of measles and scarlet fever is desirable, and all therapy should be directed toward its encouragement. Whenever a case of measles or scarlet fever with high temperature and other toxic phenomena shows but a scant and incomplete eruption, I practice and advise the giving of a warm bath followed by a dry pack. The perspiration which ensues is generally successful in bringing out the eruption, while at the same time the temperature will sink materially and the curve be completed on a lower plane.

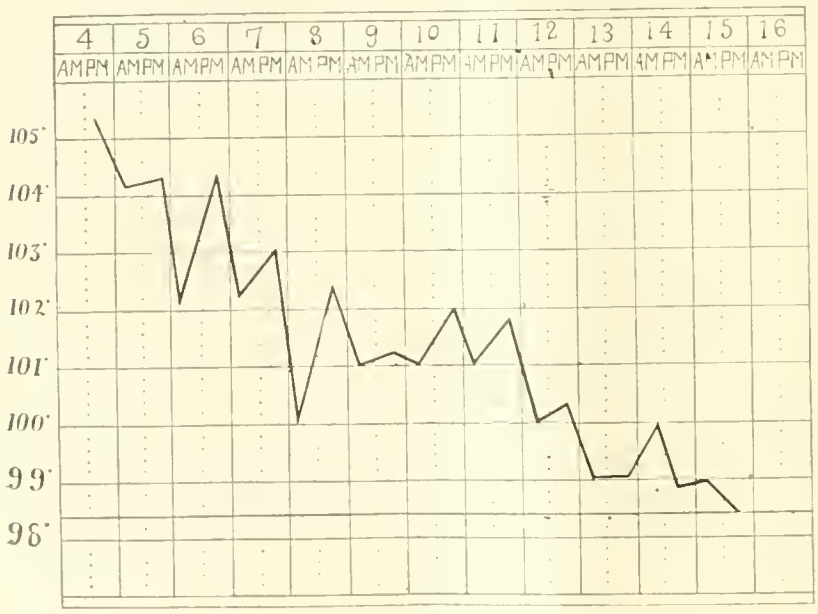

Chart 16. Scarlet Fever, Defervescence. Elsie K.

This is only done if with hyperpyrexia the eruption is incomplete. To reduce abnormally high temperatures (above 104°) in uncomplicated or complicated measles or scarlet fever, I have used for some years the following method: The patient is placed in a bath with the water at a temperature of 80° F.; at the end of five or ten minutes, depending upon the case, the temperature of the water is raised to 90° by the addition of warm water. A bath at 80° for a fever patient with temperature of 105° is a cooling bath, and yet not cool enough to produce the evil effects upon the capillaries of the skin of which I spoke above. The subsequent *raising* of the temperature of the water ten degrees for ten minutes is equivalent to giving a warm bath after the cool one to the patient who has become accustomed to the water at 80°. Whatever ill effect the cool bath

at 80° may have had upon the cutaneous capillaries and nerves is more than counterbalanced, and yet the temperature of the bath is still at 90°—much lower than that of the skin. The patient, when taken from the bath, is wrapped lightly in a sheet and covered lightly by a thin blanket. The temperature will be found to have declined from one and one-half to three or more degrees, and the decline persists longer than from any other method that I have tried in these diseases. Moreover, the eruption is not diminished, the pulse is improved, sleep generally induced, and a gentle perspiration covers the whole body. Practically, one point of importance must not be forgotten. When the warm water is added it must be poured into the bottom of the bath tub. The reason for this is that if the warm water is poured on the top, it floats over the cool water, unless imperfectly mingled mechanically by the nurse. The patient would thus have the lower part of his body bathed in cold water and the upper part in warm or hot water. For this purpose I have used in private houses a tin funnel with a piece of rubber hose long enough to reach to the bottom of the tub, and thus the warm water is delivered at the bottom of the bath. It then rises by its own lightness, as compared with the cold water, and is disseminated throughout the bath. For hospitals, a tub with a false fenestrated bottom can be made, and a permanent tin tube passed along one of the sides to the bottom, to accomplish more easily the same purpose. The patient should not be rubbed after such a bath, both because the warm additional water accomplishes all or more than the rubbing in the Brand bath, and for the further reason that friction is detrimental to the inflamed skin, producing a pseudo-desquamation long before the subjacent skin is ready to cast off its inflamed covering. Such desquamated areas of skin are practically superficial ulcers.

Lesser degrees of hyperpyrexia are treated by sponging with water at 70°, to which one-third ordinary alcohol has been added. The alcohol in these cases acts the part of the added warm water in the bath, and counteracts the ill effects of the cold sponging upon the capillaries and nerves of the skin. It is unnecessary to again repeat the injunction against the use of friction upon the skin. On the contrary, the sponging should be liberally done with a large soft sponge, only the excess of water absorbed by patting the skin with a soft towel and the patient lightly covered as after a bath. Of these two methods the most efficacious in very high temperatures of scarlet fever and measles has been the tub bath as above described.

With a knowledge of what is the normal and expected course of the temperature in uncomplicated cases of these diseases, we should be able from carefully kept charts to receive much aid in the differential diagnosis of these affections when they resemble each other, in the early recognition of complications and in the prognosis of individual cases. We should be able to estimate at their true value specific sera that may be recommended for the treatment of measles and of scarlet fever by their effect upon the normal temperature curve. The efficacy of the methods I have described for the treatment of hyperpyrexia in these conditions will be my excuse for a conscious offense against unity, in thus discussing or combining in one paper two closely allied, but yet separate and distinct topics.

The charts from the cases in the Riverside Hospital were furnished me by Dr. Watson, acting resident physician, and Dr. Horwitz, interne, at the Riverside Hospital, to both of whom I hereby express my sincere thanks.

923 Madison Avenue

GRAVE ANÆMIA DUE TO HOOK-WORM INFECTION.*

By LOUIS M. WARFIELD, A.B., M.D.,
SAVANNAH, GA.
FORMERLY HOUSE MEDICAL OFFICER OF THE JOHNS HOPKINS HOSPITAL.

The recognition of the true etiology of a group of anæmias prevalent in our Southern States is of comparatively recent date, and the rôle played by the intestinal worm, *Uncinaria americana* (Stiles) is as yet little appreciated. The succession of events from 1901, when Stiles made the suggestion that we probably had in our midst a worm similar to, if not identical with, that found in Egypt, Europe, and the Tropics, which caused the so-called "brick-makers' anæmia," "miners' cachexia," etc., to the present status of Uncinariasis, has been both rapid and startling. Who would have supposed that within two short years all our ideas of one group of anæmias, in the South especially, would be so upset? From time immemorial malaria and the miasm of swamps have served as diagnostic rubbish heaps, where practically all cases of anæmias were indiscriminately thrown. Now, however, thanks to the labors of Stiles, Ashford, Harris, and others, we are waking up to the fact that we have a disease easy to diagnose and easy to cure that is responsible to a great extent for the lifelessness and unproductiveness of the country communities. Strange it is that a disease so easily recognized should so long have waited to be accurately diagnosed. It represents a triumph for science and microscopical methods in the hands of earnest seekers after truth.

The cases reported are few. Case 5 in particular is the only one of its kind that I have seen or heard of. The interest lies in the fact that it suggests possibilities of mistakes in diagnosis, and for this reason more than any other I present the case. First, let me relate briefly the histories of four other cases:

Case I.—Wm. C., age twenty, white, comes from Higgston, Ga., admitted to the Savannah Hospital, August 18, 1903, complaining of sores on penis. He says all his family are tall, well-built people. The patient up to ten years of age was well, except for chicken-pox. At age of ten he had rheumatism, which confined him to bed for nearly three years and left him a cripple. He has had ground-itch five times, the last attack three years ago. He lives among the piney woods on sandy soil, and says that many sallow people are in the town. Three months ago he contracted a venereal sore, which was diagnosed as chancroid. He has lost in the past year some weight and much strength. For our purpose his present illness began about ten months before admission. He began "to go down hill," felt drowsy all the time, and had a disdisinclination to move around. Does not think his disposition has changed. No loss of appetite, no diarrhœa at any time, and he never noticed that his stools at any time contained blood. Has suffered with shortness of breath and palpitation of the heart. Physical examination shows the patient to be undersized, underdeveloped, and dull intellectually, about 5 feet 3 inches in height. Small dressing on bridge of nose where abscess was opened. Walks on crutches. Complexion sallow, mucous membranes pale; very few vessels can be seen in conjunctivæ. Sclerotics of normal whiteness, pupils slightly dilated, equal, react normally. Soft systolic murmur at second left interspace. Heart not enlarged. Pulse regular in force and rhythm, good volume, rather low tension, 20 to ¼. Abdomen flat, no tenderness. Spleen felt extend-

*Read before the Georgia Medical Society.

ing 6 cm. below costal margin. Liver not enlarged. Healing sores on penis. Testicles small, no nodules. Legs show typical picture of arthritis deformans. The patient was seen by me on September 16. A specimen of stool showed numerous ova of uncinaria in all stages of segmentation. The stool had a peculiar granular appearance, dark brownish-red in color, with a curious odor which was not disagreeably fecal, combined with an odor somewhat resembling stale blood. A piece put on a sheet of white paper and allowed to stand for an hour left a reddish-brown stain, which is said to be of diagnostic value.

September 18.—Thymol was given in divided doses, followed by castor oil. All stools were lost. Since admission the patient has had an irregular temperature, reaching almost every afternoon to 99° or 100° F., returning in the morning hours nearly to, or quite to, normal.

September 19.—Temperature subnormal, and up to the time of discharge on September 26, it was never 99° F. The patient was given two other courses of thymol, but through some misunderstanding all the stools were lost.

September 25.—Discharged at his own request. He is much improved, but a few eggs are still to be found in the stools.

Case II.—Wm. S., age eighteen years, Screven, Co., Ga., complains of shortness of breath and feeling badly. This patient was under the care of Dr. Carter, at whose suggestion I examined the stools. The patient says his family are well. All are full-sized. His father used to be sickly, but now seems quite well. He himself has always been sickly. Used to feel tired and drowsy, and was subject to attacks of diarrhœa. He has had repeated attacks of grounditch, the last attack two years ago. For some time he has been a messenger boy. His health at present is much better than it ever has been. The patient was seen by me on September 24. He had been under Dr. Carter's care for several months, and had improved considerably under treatment with iron and tonics. He had had a dilated heart and all the symptoms of grave anæmia. He had constantly a low fever from 99° to 100° F. *Status præsens*: A markedly sallow, underdeveloped boy, cheeks puffy and skin tough, parchment-like, yellowish in color. Mucous membranes exceedingly pale, lips dry and full of fissures. Eyes bright, pupils not dilated, react normally, tongue clean. Chest small, but normal; lungs negative. Heart's apex in fourth interspace inside nipple line. No increase in dulness, no thrill. A soft systolic murmur heard all over left chest, loudest at second left interspace. Arm and legs thin. Abdomen a trifle full. Spleen and liver readily felt; no œdema. Genitalia not developed. Stool formed, same characters as Case I. Very numerous ova found on microscopical examination.

September 27: Thymol given, followed by castor oil. A small specimen of stool passed at 4 P.M. seen. All other stools lost.

September 28: Blood count: reds, 4,152,000; whites, 10,500; hæmoglobin, 43 per cent. Stained specimen showed numerous eosinophiles; slight irregularity in the size of the red cells; no nucleated red cells seen. The patient was discharged September 29.

November 10: On microscopical examination of a specimen of stool many eggs are still seen. The patient says he never felt better in his life. He is gaining weight and color.

Case III.—Harry W., white, Camden Co., Ga. I am indebted to Dr. Corson for permission to report this case. The patient was born in Syracuse, N. Y. He was taken by his parents when a few months old to Camden County, where his people have since lived. He entered the Savannah Hospital October 3, 1903, complaining of a gunshot wound of the right arm. His parents are living and well. He has three brothers and one sister, all of whom look pale and sallow; have had repeated attacks of grounditch, and chills and fever. He has always been well, except for attacks of chills and fever, occurring, as a rule, in the fall. He has had repeated attacks of diarrhœa, but has never noticed blood or mucus in the stools. His appetite is good. He goes barefoot, and has had several attacks of grounditch. He does not admit much shortness of breath or palpitation of the heart. He says that near where he lives are many people who eat pine straw, and are said to eat dirt. He is sallow, yellowish, anæmic, quite intelligent, eyes bright, sclerotics have a slightly yellowish tinge. The conjunctivæ are almost white, tongue slightly coated. A hæmic murmur heard at the second left interspace, and a palpable spleen which has a hard fairly sharp edge, are the only points of interest. The right arm is bandaged from wrist to shoulder, and is laid on a pillow. He has had a slight rise of temperature since admission. October 9: A stool obtained was yellowish brown, homogeneous. On microscopical examination a number of ova of uncinariæ were found. Blood count: reds, 2,596,000; whites, 9,000; hæmoglobin, 48 per cent. No malarial organisms found in fresh smears of blood; some pigment seen. All red cells are of equal size; eosinophiles not numerous, but appear slightly increased in numbers. October 10: The patient was given thymol, followed by castor oil.

November 10: No eggs were found in the stools after careful search. The patient has more color and says he feels better than he has ever felt.

Case IV.—Gussie M., age fourteen, white, Waycross, Ga. Admitted November 12, complaining of fever. Family history negative. She has always been well, but has never been very strong. She has always been pale, suffers from shortness of breath; has never had diarrhœa; appetite good. Menstruation began at age of twelve, and has always been regular and painless. She has had several attacks of grounditch, the last attack two years ago. She has never had malaria. While in South Carolina recently she had dumb chills, followed by sweats. No vomiting, no nausea, some headache; loss of appetite. Hyaline æstivo-autumnal malarial parasites were found in fresh smears of blood. Temperature on admission was 101°F. She was given quinine, and in a few days her temperature was normal, and has remained so ever since. She is a well-nourished pale, sallow, girl, fairly intelligent. The mucous membranes are pale, the sclerotics have a slight yellowish tinge; pupils normal. Soft systolic murmur at second left interspace. Large tumor in abdomen, which is an eight months' pregnancy. Spleen not felt. Stool examined November 16 was brownish, fairly homogeneous. Numerous eggs were found on microscopical examination. Blood count: November 19, reds, 3,920,000; hæmoglobin, 55 per cent. Stained specimen showed one crescent; red cells slightly irregular in size; nucleated red cells seen; no noticeable increase in the eosinophiles. Patient not to be treated until after delivery.

Case V.—This is the case to which I wish particularly to call attention. It illustrates one phase

of the infection with hook-worms which I have suspected occurred, but so far have seen but this one patient. Lina T., age twenty-one, white, single, was seen on November 10, when she complained of pain in the back, chilly sensations, and fever. She comes from Screven Co., Ga. Both parents are dead, causes unknown. She has two sisters and two brothers living in Savannah. All are well, except a younger sister, who is pale and sickly. She has always been sickly, and has never been able to do much work, as she tires very easily. She had scarlet fever two years ago; no sequelæ. She had chicken-pox when a child. Up to two years ago she had grounditch every summer; the attacks were severe. Menstruation began at age of fourteen; her periods have always been scanty, irregular, and accompanied with some pain. She has had at times a slight leucorrhœa. Occasionally her feet and ankles have swollen, but she has had no urinary troubles. She has had some irregularity of the bowels, and attacks of diarrhœa. Appetite usually good. She works in the American Cigar Factory here. On November 10 she was seized with chilly sensations, pain in the back and loins, and fever. For several days previously she had been feeling unwell. The pains were so severe that she was forced to go to bed. She has had no trouble in passing urine, did not think it was abnormal in color, and she has had no suppression. Bowels regular, appetite lost. The patient was seen at night by the light of a small lamp. She was lying on the right side, and seemed in pain. A fairly well-nourished girl, but markedly anæmic, skin pasty white; eyes puffy; mucous membranes pale; tongue slightly coated; lips fissured; the under lip showed herpes, and several excoriations. Pulse 30 to ¼ regular; low tension; fair volume. Temperature 101.4° F. There were a few râles in the lungs at the bases. A loud systolic murmur was heard all over the left chest in front; loudest at the second left interspace over the pulmonary area. No thrill was felt. The apex beat was inside the nipple line in the fourth interspace. Abdomen negative, except for pains in both loins on deep pressure. There was distinct œdema of both shins, knee-jerks normal. There was no specimen of urine but the signs and symptoms were so suggestive of a nephritis that she was treated as such, and she was told to have a specimen of urine ready at the visit next morning. November 11: This morning there is no fever. The complexion is seen to be sallow, parchment-like. Her anæmia is seen to be profound. A specimen of stool was obtained and the suspicion of uncinariasis was confirmed by finding enormous numbers of eggs. The stool was exactly like that described in Case I. Urine examination showed a clear urine, slight flocculent precipitate acid, sp. gr. 1012, no albumin, no sugar. November 13, temperature 99.4° F., pulse 30 to ¼. The patient is up and says she feels about as usual.

Blood count showed red cells 3,160,000, hæmoglobin 27 per cent. In a stained specimen one sees that the red cells stain faintly; they are irregular in shape and size and show some chromatophilic degeneration. There is a decided increase in both the eosinophiles and small mononuclear cells. Normoblasts are also present. The patient was sent to the Savannah Hospital, where she could be observed and treated better than at home.

November 14: Temperature 99.6–100° F. Thymol was given in divided doses, followed later by castor oil. In the stools large numbers of male and female uncinariæ were found. November 16: Temperature 98.6–99° F. Thymol was again given, followed by castor oil. A number of worms were found in the stools. November 18: Temperature has been normal since last note. Discharged improved. December 20: The patient has gained in flesh and strength. Eggs are still found in the stools. She will be given another course of treatment.

These few cases serve to illustrate the point that I wish to bring out, viz., that in cases of anæmia one should always examine the stools for intestinal parasites. If the case has come from the country, a child or young adult, and gives a history of previous grounditch and attacks of diarrhœa, one is sure to find eggs of the hookworm in the stools. The number of eggs found is, as a rule, in proportion to the severity of the anæmia.

From studies that I have been able to make around Savannah, I am led to the conclusion that (1) The anæmias of the country districts are due in the great majority of cases not to malaria, but to uncinariasis; and (2) that in almost all cases of uncinariasis there have been previous attacks of grounditch. That the connection between these two diseases is a close one seems beyond doubt. The idea was advanced by Looss only two years ago, but evidence is daily accumulating tending to show the intimate relationship between the two conditions. Bentley has found in the water sores of panighao, which evidently is similar to our grounditch, embryos which he identified as those of *Ankylostoma duodenale*. That is very significant, and I believe that when grounditch is carefully studied in the light of our present knowledge, we shall have ample confirmation of his work.

Elsewhere I have expressed the belief that uncinariasis may at times give rise to a fever simulating typhoid or æstivoautumnal malaria. That there is a long-continued fever in the severe grades, three of the foregoing cases show. One shows that an acute exacerbation of a puzzling character may take place. In such cases it is of paramount importance to make an exact diagnosis, otherwise whatever treatment we use only temporarily betters the condition. From the histories and general appearances, cases of uncinariasis may resemble those of pernicious anæmia. The examination of the stools alone settles the diagnosis. The blood conditions in the two diseases may be similar except for the eosinophilia, which always occurs in grave cases of uncinariasis. One condition is easily curable, the other is rarely ever cured.

For a proper interpretation of microscopic blood changes, however, special training is necessary, whereas any one who can see through a magnifying glass can look for and recognize uncinaria eggs under the low power of a microscope. A small piece of stool the size of a pin-head is put on a slide and mixed well with a drop of plain water. On this a coverslip is dropped and the slide then examined with Leitz ocular 3, objective 3. In cases of severe infection one usually focuses immediately on an egg, and one sees at times ten or a dozen eggs in one field of the microscope. The whole procedure takes not longer than a minute, hence no one should ever be too busy to devote that time to making an accurate diagnosis on his patient. This is all the more important when we know that the treatment is so simple and generally so successful. Without the diagnosis no treatment is of any avail that does not attack the cause of the trouble. With our present knowledge we may be morally certain of hook-worm disease from the history and general appearance of the patient, and if there is no means of verifying microscopically our suspicion, we can give specific treatment and tell the patient

to look for small, thread-like worms in his stool, and have him bring a specimen for inspection. The truth is that we must all lay aside our preconceived notions that all anæmias and all sallow complexions can be caused only by malaria, if we have any such ideas, and lay it all to hook-worm infection until we prove any individual case to the contrary after careful stool examination. It is far better that the pendulum should swing completely over, and that we should believe all anæmias to be due to hook-worm infection and none to malaria, than that we should jog along as we have done and yearly sacrifice thousands of lives on the altar of inherent prejudice to new ideas. Let the profession at present look with suspicion on grounditch, preventing it whenever possible, and when present curing it without delay. Let us take the attitude of the Saxons that a man is guilty until he is proved innocent and apply it to grounditch. We may be mistaken in laying so much stress on an antecedent grounditch as the cause of hook-worm disease, but the facts at present at our command warrant us, in the writer's opinion, in believing such an hypothesis.

It is also of interest to note that in high grades of anæmia, from whatever cause—neoplasm, hemorrhage, pernicious anæmia, uncinariasis, malaria, etc.—there may be œdema and even anasarca, and there is in most cases some fever. The fatal termination is at times preceded by delirium, high temperature, and even mono- or hemiplegia.

The treatment of the cases is simple and successful, although in severe cases it is necessary to continue specific treatment at intervals until the stools are free from eggs. One gives an adult castor oil or Epsom salts in the evening. There must be no food whatever given from then until noon of the following day. At 8 A.M. 30 grs., 2 grams, of finely powdered thymol are given either in capsule or with a little water. At 10 A.M. another dose of 30 grs., followed at noon by a large dose of castor oil or salts (℥ I–II). In order to facilitate the action of the thymol some give whiskey or brandy with it, but as the combination has proved on several occasions to possess distinct depressing and toxic actions, it is safer to administer the drug in capsules or with water alone.

Finally, let me urge my fellow-practitioners to be on the watch for cases of anæmia, especially in children and young adults who come from the country. I know that some of you do not agree with me when I lay so little stress on malaria as a cause of anæmia. I ask you to take careful histories, make, when possible, blood and stool examinations, and I feel sure that before you have made many such examinations you will agree with me that it is the hook-worm that causes, and has caused, such suffering to our country people. It is with us in the South a serious economic problem, and we cannot start too early to band together to fight it intelligently.

Percussion of the Pulmonary Apices.—Jundell discusses the possibilities of making errors in doing this, and especially the fact that percussion is very apt to be carried too far to one side or the other. He suggests that in percussing the supraclavicular fossa, a point be selected which lies just above the clavicle and at the outer border of the clavicular portion of the sternomastoid muscle. The finger should be so placed that its volar aspect is directed backward and only very slightly downward and toward the median line. When percussing the fossa supraspinata the same precaution should be taken to place the finger so that the percussion stroke is at right angles to the surface of the lung.—*Zentralblatt fur innere Medizin.*

ACUTE TETANUS CURED BY INTRANEURAL INJECTIONS OF ANTITOXIN.

By JOHN ROGERS, Jr., M.D.,
NEW YORK.

The following case corroborates very strongly the experiments with tetanus in animals which demonstrate the curability of the disease by injections of antitoxin into the motor nerves of the part primarily infected.

J. M., a boy of eleven years, sustained a punctured wound of the sole of the left foot from a rusty nail. This occurred on the afternoon of Monday, April 25, 1904. No attention was paid to the injury, and beyond some soreness no symptoms resulted until seven days later, or Monday, May 2. On arising at 6 A.M. this day he complained of some stiffness about the jaws and neck and was unable to eat breakfast.

He was brought to Gouverneur Hospital at 10 A.M., where examination revealed marked trismus with risus sardonicus and stiffness and rigidity of the muscles of the back of the neck. There was a small punctured wound in the anterior part of the sole of the right foot just to the outer side of the ball of the great toe. Pulse 110. Temperature 99°. He was immediately put to bed and given 20 c.c. of antitoxin subcutaneously and this dose was repeated in the afternoon. At 6 P.M. the rigidity of the neck had extended to all the muscles of the back and the jaws were tightly closed.

May 3. During the night the condition had become worse and the apisthotonus was so marked that he was placed on his back with pillows under the lumbar and shoulder regions to relieve somewhat the strain from the backward extension of the head and legs. At 11 A.M. Dr. Elliot, under whose care the case had been, kindly consented to allow me to try the efficacy of the intraneural injections of antitoxin which had proved so successful in the previous case, and therefore under chloroform anæsthesia, with every antiseptic precaution, the anterior cruræ nerve was exposed just below Poupart's ligament and about ℥ ss of antitoxin injected into its substance. The same procedure was adopted with the great sciatic nerve opposite the gluteal fold posteriorly. A rather fine needle was employed, and while the nerve was held on the index-finger the needle was several times withdrawn and reinserted into the substance of the trunk to insure some wounding of the nerve fibers, as experimentally this seems an essential matter to secure entrance for the antitoxin. The patient was then turned over and the needle introduced into the spinal canal between the laminæ of the second and third lumbar vertebræ. The needle was manipulated back and forth in the spinal canal until its motion produced a twitching of the left leg (the right leg contained the source of infection). This was intended to make at least an abrasion of some of the nerves in the cauda equina, and the twitching was considered evidence of the success of the manœuvre. The escaping cerebrospinal fluid contained no blood. Antitoxin ℥ iss, was then injected into the spinal canal subdurally. The wound in the foot was next laid widely open, a small foreign body, apparently a piece of leather, and a little pus and necrotic tissue scraped out and the raw area swabbed with tincture of iodine and packed with iodoform gauze. A culture made from the wound was reported later by Dr. Letchworth Smith, bacteriologist at the Cornell Medical College, to contain numerous tetanus bacilli. At the conclusion of the operation there was found to be a noticeable relaxation of the rigidity, which persisted until recovery from the effects of the anæsthetic (chloroform). This relaxation occurred with each

subsequent anæsthetization and seemed to me of appreciable benefit. During the night following (of May 3) the condition again grew worse and there were four separate convulsive seizures, each lasting about ten minutes.

May 4. The condition seemed hopeless; the opisthotonus was, if anything, worse than in the previous morning, but there had been no recurrence of the convulsions noted in the early part of the night. Not even water could be given by mouth. The temperature was 103° and the pulse 120. As the outlook could not be made worse, I decided to make one more trial of the antitoxin near the vital centers, and therefore, under chloroform anæsthesia, inserted a rather fine needle with a long point into the spinal canal between the laminæ of the second and third *dorsal* vertebræ. After the needle was felt to pass between the laminæ it was pushed on until it impinged against the bodies of the vertebræ in front. In other words, an attempt was made to puncture the dorsal cord, and though no blood tinge occurred in the escaping cerebrospinal fluid, I cannot see how the cord could have escaped some wounding by the long, fine point. At any rate, ʒ iss of antitoxin was injected while the tip of the needle was felt to touch the posterior surface of the vertebral body. The only reaction noted was marked contraction of the pupils and a slight slowing of the pulse. Opportunity was taken of the anæsthesia to redress and swab with tincture of iodine the wound in the foot.

During the rest of the day and through the night a very remarkable improvement took place.

May 5. In the morning it was found that no convulsions had occurred. The rigidity of the back and legs had largely disappeared and the mouth could be opened about half an inch. The improvement was so great that it forced me carefully to review the previous conditions, and then for the first time I made the humiliating discovery that in injecting the motor nerves of the leg I had entirely overlooked the obturator. The source of infection had probably been entirely eliminated at the first operation and the charge of poison on its way to the cord in the two chief nerves, the sciatic and anterior cruræ, blocked, but the charge in the obturator had been allowed to flow upward and almost produce death. It had been stopped from reaching the vital centers only by the antitoxin injected ahead of it into the upper end of the cord. Whatever the explanation may be, the value of injecting motor nervous tissue and of previously producing a wound of this nervous tissue for the entrance of the antitoxin seems to me abundantly proved by the injection here into the dorsal cord. The condition of the patient was changed within a few hours from one of impending death to one of comparative well-being. And there is the less possibility of exception from this view because of its close analogy with the experimental results previously referred to in the work of Meyer and Ransom.

May 6. The condition of the patient was found on this day to have deteriorated somewhat from that noted during the previous twenty-four hours. It was so excellent on May 5 that no antitoxin had been given, but on May 6 the trismus had returned with some stiffness of the neck and back. Liquids which could be taken freely by mouth yesterday could not now be managed so well and had again to be supplemented by rectal alimentation. A lumbar puncture was therefore performed (under chloroform) and in manipulating the needle to wound the nerves there was produced a considerable flow of blood, perhaps half a drachm mixed with cerebrospinal fluid. But without waiting for it to cease ʒ iss of antitoxin was injected subdurally. The only result noted was contraction of the pupils and slight slowing of the pulse. During the afternoon and evening the patient seemed more comfortable and mouth feeding was resumed.

May 7. The patient seemed perceptibly improved and could separate the teeth about half an inch. The neck and back were still quite rigid, but the extremities were entirely relaxed. As no harm could result, and to forestall any possibility of relapse, another dose of ʒ iss of antitoxin was administered by lumbar puncture. No more was given subsequently.

May 8. Slow, but evident gain. In the past twenty-four hours he has been able to roll about in bed and professed to feel perfectly well if only he could "cheer."

May 9. The improvement continues, though the trismus has not entirely disappeared, and did not until May 13. During the afternoon an extensive erythema began to appear on the abdomen and legs. On the following day this had spread to involve the whole trunk and had almost the appearance of purpura hæmorrhagica. But the pulse and temperature continued low, and on May 13 the rash had entirely disappeared as well as all the symptoms of tetanus. The wound over the anterior crural nerve had failed to unite and became infected. The wound in the sole of the foot was of course granulating and open. The wound over the sciatic had healed. He was eating regular house diet, and on May 18 he was out of bed and pronounced cured.

To my mind the progress of this case has demonstrated without a shadow of doubt the efficacy in tetanus of injections of antitoxin into the substance of the motor nerves of the part of the body primarily infected and into the spinal cord. From the wonderful and rapid change for the better noted after injecting the antitoxin into the dorsal cord on May 4 it might be argued that the motor nerves could be neglected, but in view of the experiments by Meyer and Ransom this would seem unsafe. The exposure of the nerves in the axilla or high up in the thigh is simple, and adds nothing to the gravity of the situation, and in the two cases I have reported really seemed very advantageous. My inexcusable neglect to inoculate the obturator nerve in this second case I am convinced led to the increase of symptoms on May 4. That they were checked by injecting the dorsal cord only goes to show the necessity of producing a wound of nervous tissue to secure entrance for the antitoxin. This, by the way, is evidently the crux of the whole problem and seems a beautiful confirmation of a physiological fact, or perhaps theory, which is as remarkable as it is unique, namely, the complete isolation of at least some nerve cells from the circulating blood. The tetanus toxin and the antitoxin can only reach these nerve cells through nervous tissue, and normally this course begins with the terminal filaments of the axis cylinders.

102 East Thirtieth Street.

Erysipelas and Nephritis.—Nyrop gives the histories of two cases in which intercurrent erysipelas appeared to cure or improve an already existing nephritis. The first, already described by Langeballe, is that of a young woman suffering from a severe acute nephritis which cleared up entirely in the course of a moderately severe general erysipelas. In the other case the albumin and casts did not entirely disappear but marked and permanent improvement followed.—*Zentralblatt fur innere Medizin*, No. 15, 1904.

THE NON-SIGNIFICANCE OF CLINICAL SYMPTOMS IN DETERMINING THE PATHOLOGICAL CONDITIONS OF APPENDICITIS.*

By A. P. STONER, M.D.,
DES MOINES, IOWA.

That the millenium in which the clinical diagnosis of the pathological conditions of the inflamed appendix is not attained, is evidenced by the experience of some of our most noted clinicians and operators. As one's experience grows with the diseased appendix, the less inclined we are to make positive assertions as to the conditions that will be met on the operating table. After having operated upon over two thousand cases, Murphy is quoted by Knott ("Transactions Iowa Medical Society," Vol. XX) as saying that "he did not pretend to know anything more of the pathology of a given case than that the patient had an inflamed appendix which should be immediately removed." Now and then we meet a case in which it is indeed impossible to say whether or not the patient has even "an inflamed appendix." In the early stages of appendicitis the pains are diversified over the whole abdomen, or may be confined to the gastric region. These phenomena are explained by the fact that the superior mesenteric plexus which supplies the appendix also sends filaments to the intestines. In some instances in which a low grade of inflammation of the organ exists, the pains never become localized around the appendix, but during each attack or exacerbation of the disease, pain may constantly be observed in the gastric region.

Case I is an illustration of this type. Michael S., professional gambler, age forty-six; no specific history. Formerly drank to excess. His infatuation for cards was such that at times he would go without his meals for from twelve to twenty-four hours, after which he would grossly overindulge in food and drink. The trouble for which he sought relief began about six years ago in periodic spells of violent pains and vomiting.

The attacks would readily pass away under proper treatment and leave no apparent trace of the disorder. He was under my observation about one and one-half years before the operation. Usually appearing after a debauch in diet, the attacks would invariably continue until relieved by opiates. When the stomach was emptied, purging would ensue. I often found him on the closet stool with a vessel between his feet, purging and vomiting at the same time, ejecting by these efforts only a little mucus or liquids. The accompanying pains could be compared only with the tortures of childbirth. Indeed I have seldom witnessed such agony from any cause. Although at this time he was not an habitué, it required from one-half to three-fourths grain morphine to alleviate his suffering. The attacks came on at varying intervals of from three weeks to three months, and would last under proper treatment from two to six days. Rectal feeding usually had to be resorted to. After the attack he would be apparently well again and could eat all sorts of food. No pains or inconveniences were experienced between attacks. The matter vomited was analyzed on several occasions and usually showed deficiency in hydrochloric acid, and the presence of lactic acid. At no time, even during the attack, was there any pyrexia. Pressure over McBurney's point could arouse no suspicion of a diseased appendix. The immediate region of the gall-bladder was apparently normal. Jaundice was never present. Even during the attack the abdomen was always flat, yet no information could be obtained from palpation, etc. The attacks became so frequent and were of such severity that the patient became reduced to a mere skeleton before finally submitting to operation. He had now become a confirmed morphine fiend, using from .5 gr. to 1.5 grs. daily. He entered Mercy Hospital August 15, 1903, and was placed upon nutrient enemas. Following this he was cautiously fed by the stomach. It was not, however, until September 19 that his condition was such as to permit of abdominal section. Under ether anæsthesia I opened the abdomen, beginning at the costal arch and extending downward three or four inches along the outer margin of the rectus muscle. I rather expected to encounter a diseased gall-bladder. This region, however, was apparently normal, as was also the stomach and pancreas. Strangely, the stomach presented no evidences of the abuse to which it had so long been subjected. The incision was extended downward to the appendix, which was found to be slightly enlarged and injected, and thoroughly adherent to the posterior border of the cæcum. After the removal of the appendix, the wound was closed by two rows of continuous catgut, and interrupted skin sutures of silk-worm gut. The belly being scaphoid, some difficulty was experienced in bringing the walls of the abdomen together. During convalescence the patient proved to be extremely incorrigible, and the day following the operation was found sitting up in the bed. Subsequently he was chastised a number of times for the same offense. The stitches were removed on the seventh day, and the second night following the nurse found him out of bed sitting upon the commode in an effort to evacuate the bowels. My attention next day was directed to blood upon the dressings, and upon removing them, the ghastly spectacle of the abdominal contents met my gaze. The wound—a seven-inch incision—had been torn open from one end to the other. He was again prepared for operation, and taken to the operating room. It required considerable dexterity and patience to coapt and hold the edges of the wound together. The tissues had become softened and the sutures easily cut through. However, by the aid of through-and-through sutures of silk-worm gut, which were tied as the continuous sutures of catgut drew together the fascia and peritoneum; the wound was thus finally coapted. The wound healed a second time by primary union. The stitches were allowed to remain two weeks, and he was kept in bed an additional fortnight. It is now four months since the operation and the patient has gained 40 pounds and feels perfectly well. He still uses morphine, however. Although a number of surgeons examined this patient with me, at no time did any of us seriously suspect that the appendix was creating the disturbance.

Case II.—The following case, upon which I operated a few weeks after the one just related, illustrates, on the other hand, the paucity of symptoms sometimes observed in the most virulent types of the disease. Mr. S. B. L., age twenty-seven, was sent me by Dr. Swartslander of Huxley, Iowa. On Friday, October 31, he experienced pains in the abdomen, and drove to town to see his doctor. The doctor found him suffering from appendicitis, and advised him to return home and go to bed. On the following Sunday some tympanites developed, and the doctor was called. A saline purge was administered and the symptoms rapidly cleared away. Tuesday he was taken five

*Specimens presented and cases discussed before the Des Moines Pathological Society, March 29, 1903.

miles to the railway station in a carriage and brought to Mercy Hospital in this city, a distance of forty miles by rail. Examination revealed an induration over McBurney's point, slightly tender upon pressure. Otherwise his condition was apparently normal. Indeed, the patient stated that at no time would he have gone to bed had not his physician and friends urged him to do so. However, he was anxious to have his appendix removed, and on the following Friday, November 6, exactly seven days from the beginning of his first and only attack, the operation was undertaken. Upon opening the abdomen, the region of the appendix presented an apparently inextricable mass of adhesions. A large mass of partly disorganized omentum, the thickness of one's hand, was finally released, and after being tied off was completely removed. In searching further for the appendix, much more semi-gangrenous tissue was encountered and cleared away. Presently I came upon a pocket containing a mass, the size of a filbert, of semi-solid fecal matter. It seemed to have been extruded directly from the cæcum, which organ was very much thickened and scarcely distinguishable from the mass of adhesions in which it was embedded. After having removed the fecal mass, and while still laboring under the impression that the cæcum had been opened, I attempted to close up the vent, but the sutures cut through the softened tissues, and the stitches were of no avail. What was thought to be the base of the appendix now became visible, but it was not possible to extricate the appendix, so thoroughly was it embedded in the exudate. The opening being guarded by gauze, a longitudinal incision was made along the visible portion of the appendix. The incision included the peritoneal and muscular coats. The mucous lining was then grasped with forceps, and while traction was being made, the incision was prolonged until the other end was reached; which was found to be the base and to occupy the posterior border of the cæcum. The supposed rupture of the cæcum proved to be a perforation in the distal end of the appendix. The core of the appendix having been freed, it was ligated and the stump cauterized and covered with peritoneum. The wound was closed without drainage. Nothing whatever marred the recovery until the seventeenth day after the operation, when thrombosis of the right femoral and saphenous veins developed. The temperature rose to 101° F., the pulse became accelerated, and much pain was experienced. This annoyance continued until November 27, when the patient was again permitted to be out of bed. He left the hospital November 31. To my mind it is almost a mystery how the insignificantly inflamed appendix in Case I could have been responsible for the profound symptoms manifested. It is none the less mysterious how one could be up and about doing farm-work with such a condition as was revealed in Case II. The deduction to be drawn from Case I is that a slightly diseased appendix may be responsible for a variety of symptoms that may be attributable to other organs. Case II furnishes additional proof that no case, however apparently mild, should be entrusted to nature or drugs.

Large Doses of Carbolic Acid in the Treatment of Plague.—Dr. J. C. Thomson gives particulars of 141 cases of plague treated with large doses of carbolic acid. One hundred and forty-four grains were given daily, divided into two-hourly doses of 12 grains each. The mortality among those so treated was only 36.4 per cent.—*Journal of Tropical Medicine.*

HYGIENE IN GYNECOLOGY.*

By C. A. VON RAMDOHR, M.D.,
NEW YORK.
PROFESSOR EMERITUS NEW YORK POST-GRADUATE MEDICAL SCHOOL; FELLOW OF THE NEW YORK OBSTETRICAL SOCIETY; NEW YORK ACADEMY OF MEDICINE, ETC.

In all branches of medicine hygiene is considered the most important factor in combating the source of disease, and so it is primarily in gynecology. Secondarily, hygienic treatment is the most valuable therapeutic agent in wrestling with women's troubles.

Therefore, to oust the gynecologist from his present status as curative agent we must primarily prevent women's diseases by attention to women's hygiene.

Starting from the very beginning the connubial bliss enters our consideration. Marriage between minors, between people, one of which is syphilitic, between near kin, between people who are by nature of their poverty unable to rear their young, ought to be prevented, if possible. For part of their offspring would naturally only appear as natural weaklings, always complaining of very natural woes, while the other would be forced by circumstances to enter the race of life before they are physically able, and thereby show themselves as physical wrecks in our general clinics.

The influence which crowded quarters with their inherent absence of cleanliness and morals have upon the female child are well recognized. The consequence of bad morale is well known. The habits of the young girl deteriorate, and moral turpitude may be traced directly to the surroundings. Not only does the poor young female child suffer from want of care of the mind in her morally corrupt atmosphere, but her body is not properly cleansed; her clothes are insufficient; her food is not well up to the standard in calorics, and last, but not least, by the attitude of her poor parents she is prevented from attending school "whenever that may be," to cure an insufficient degree of ignorance which will be propagated on the next generation. Their interest will lie in making the little girl a self-supporting wage-earner at as early a date as the lax law will permit. Bent over the shuttle, or bending over other work like sewing, sewing in a sweat-shop, or working in crowded factories for abnormal hours, the little girl lays the foundation of future sickness.

Still wealthier parents' girls are hardly any better off. The bottle cannot equal a mother's nourishment and care. Children's balls are not conducive to a better standard of womanhood. A fashionable school will not help to raise the morale or the physique of a fashionable girl.

Thus, in trying to avoid, or make other people avoid any of the previous delicto of hygiene we stand as gynecologists on the point where we ought to stand regarding the prevention of women's troubles by hygiene.

Now, supposing that we get in contact with a patient suffering from some female trouble, let us remember the great axiom "*Mens sana in corpore sano,*" and as a corollary: *Nullus uterus* (+ *adnexa*) *nisi sanus in corpore sano.* Ergo *Mens sana* = *Uterus sanus, i.e.* a healthy body contains a healthy mind, and a healthy uterus (and adnexa).

To the greatest extent our patients suffer from subjective symptoms—they complain of pain, and consequently their nervous system is affected. They must be treated in a surgical way if necessary, or by medical therapeutics, either by medicinal agents or by hygiene.

*Paper read at a meeting of the New York Obstetrical Society.

The first thing for us gynecologists is to make a thorough and complete diagnosis. By exclusion, by objective examination, the cause of our patients' trouble ought to be established, should such require surgical interference—for example, for tumors benign or malignant, pus collections, repair of lacerations, removal of degenerated mucous membrane, dilatation, dislocation—in fact, anything that would objectively show a degenerated organ or interference with normal functions—well and good, let our proper surgical demanded work precede all other curative measures, always keeping in mind that this is done for a subjective painful symptom for which the patient is likely to consult us, and which we are trying to relieve.

But these are not surgical procedures but makeshifts, if we remove organs not unhealthy, diagnosed because patients complain of pain in their respective regions.

We are past the period of clitoridectomy, past the period of oophorectomy and salpingectomy, past even the period of nephropexy, and last, but not least, indifferent curettage for subjective symptoms only. I say, we are, I mean the Eastern gynecologists, and the people in the West, South, or North who are abreast of the profession.

Only lately I came across a female wreck, who had been carved by a St. Louis artist, and after four operations had both her kidneys anchored, appendix, uterus, and adnexa removed, and who begged pitifully for the relief of pain for which she originally consulted her physician. All operations make a strong impression on the woman's mind, relieve her of her complaint, but only for a certain time.

Massage of the uterus and adnexa so grandly introduced have failed, except in certain selected cases. The rest cure has only lately fallen asleep. Hypnotism and suggestion, Christian Science, and hydrotherapy, and Kneippism are looked on through different spectacles from formerly. Nowadays each up-to-date gynecologist tries the newest fad, *i.e.* electricity in one or the other forms. But if the nerve specialists acknowledge that this therapeutic agent will only act curatively in 25 per cent. of their cases while 75 per cent. are benefited only by the sensations, what is there in gynecology to permit the indiscriminate application with a view of curing the disease? We may relieve symptoms but not cure the cause. Let us now consider the local treatment of uterine affections. Deviations of the uterus which produce painful symptoms or may be the cause of sterility will, of course, be benefited by restoring the organ to its original position.

As we know that almost a majority of copulating women's troubles are the result of the gonococcus, God bless our confrère Noeggerath for his invention, and Lawson Tait for his original technique—the local effort of stamping out the cause will be of the highest importance. Hot or cold douches for inflammatory troubles plus glycerin tampons cannot be dispensed with. Whether paintings with one or the other agent for plain endometritis are of any but impressionable advantage, I have my serious doubts.

Medicinal agents are good either as a placebo or as aperients or ferruginous compounds, as most of our patients are subject to anæmia and constipation. Ergot has prevented many a fibroid operation, but of all others, practically, I have my doubts.

Knowing that all aches and pains (and it is primarily the object of finding relief from those that the gynecologist is consulted) are the result of sensitiveness, and as sensations are relative and a subjective symptom which cannot be appreciated objectively by any other person, and knowing that otherwise healthy women are least sensitive comparatively, therefore, a course of general treatment can only conduce to the health of the individual—that is, in our case to the female patient. This general treatment is called hygeine. Any and all women will be benefited, and some will be restored to health and happiness.

Being consulted by a patient, and having heard her complaint, which practically will consist of pains in the back or abdomen, leucorrhœa, etc., after having carefully excluded heart, kidney, lung trouble, etc.; after having carefully excluded a diseased or misplaced genital organ which might need surgical or local treatment, it behooves us to inquire carefully into the marital relations, the mode and frequency of coition, the means taken to prevent conception, and remedy whatever is possible in this direction. To go into details would be an insult to your intellect.

The house surroundings and mode of living ought next to be studied; whether the patient is kept too warm, or too cold, whether the fresh air supply is sufficient (open windows, ventilators, heating apparatus, etc.); what an amount of care she takes in the household management, or what work she performs, what food she partakes of or craves for, the hours of meals, the recreations—reading, for example, the theater, balls, parties, or athletic exercises, etc., what stimulants she partakes of, or what narcotics (alcohol, coffee, tea, tobacco, morphine, chloral, bromine, etc.), and in what quantities. The care of the skin and teeth is next in order, and last, but not least, her mode of dressing: shoes, heels, corset, underwear. That her stools ought to be attended to is self-understood; also the general care of the period of menstruation; ditto the support of a pendulous abdomen.

Once more I only need mention these points to remind you of their importance.

There is but one point more to which I would call your attention. Physical exercise is usually overdone, unless carefully prescribed and superintended. Six-ounce dumb bells are better than two-pound ones. A walk of half a mile is better than one of several miles if it tires the patient.

It is with this graduated and superintended hygiene that the well-known watering-places in Europe obtain their stupendous results. In the treatment of females: Absence from home influences and the husband; fresh air, baths, and spongings carefully administered; carefully prescribed exercises, attention to diet and digestion, early hours—all these hygienic measures do more toward curing a patient of her symptoms than long continued local or symptomatic treatment indiscriminately employed.

45 Irving Place.

Typhoid Fever and Its Treatment.—B. A. Bobb present the following conclusions: (1) Typhoid fever is self-limiting disease which can often be modified and shortened in its course, and often aborted if treatment is instituted early in the course of the disease. (2) Where early eliminative, antiseptic and hydro-therapeutic treatment is instituted there is not the dry tongue after the first few days. The tympanites is absent or nearly so, and there is not the exhaustive diarrhœa. (3) The temperature is easily controlled by sponge baths. (4) There are cases wherein complications develop that will call for a most careful study of the case in question. (5) It is the duty of every physician who has cases of typhoid fever in charge to use every prophylactic measure to prevent those who have the care of patients thus afflicted from contracting the disease.—*The Medical Herald*, March, 1904.

COLLEGIATE TRAINING OF WOMEN.

THERE has arisen among civilized women within the past few years a great desire to compete with men in whatever callings of life are open to both sexes. This new departure on the part of women has been especially noticeable in the United States. In order to qualify themselves to meet men on anything like equal terms in the battle of life, women have recognized the fact that they must, as far as is possible, be well equipped for the fray. Consequently female colleges have sprung up like mushrooms in all parts of this country. To a lesser extent this statement is true also of Great Britain. As to the wisdom of this course opinions are greatly divided, but the weight of evidence would seem to show that women in encroaching upon fields which have hitherto been occupied solely by men, on the whole, have been ill-advised. Of course, it is well understood that some women must go out of their own groove of work and earn their livings outside their homes. It is, however, a grave question as to whether this tendency has not been carried to excess, and whether the race has not suffered, at any rate in America, through women deserting their domestic duties for a life which is contrary at least to the traditions of their sex.

Is a collegiate training harmful to women? The majority of medical men are of the opinion that such is generally the case—at all events, that co-education is harmful to women—and hold the view that women are not fitted physically for the strain put upon them by strenuous professional or business careers.

In the *Edinburgh Medical Journal* for May, 1904, Dr. T. Claye Shaw deals with this matter from his own point of view, which it may be asserted is probably the point of view of nine-tenths of the medical profession. The writer points out that those best able to judge of the evils of college training for women are medical men attached to such institutions, and their experience is to the effect that stress of competition presses in too indiscriminate a way upon the young women who are brought together and educated in very large numbers. In the opinion of Dr. Shaw, the forcing system in vogue in colleges both for men and women at the present time is good neither for the quick-witted nor for the moderate or dull girls. The former, indeed, perhaps suffer the most, for their readiness at work and the pressure that is put upon them to accomplish an end at all risk, though at times compassed with impunity, often ends in disaster and evil after-consequences. The writer also thinks that the results of these distressing efforts to compete with man on his own ground are decidedly barren. A few succeed in their university curriculum, and may be said to have found their true metier, but, in the words of Dr. Shaw, "It does seem as if the altruistic and sympathetic side of the woman's character is destroyed by the process of the new education, which substitutes a cold formalism for the warm spontaneity which dominates the majority of the sex."

If women desire a university education they should be separated from men in their work, as in addition to the competition in intellectual pursuits the entire trend of co-education is toward the elevation of the purely intellectual, and the disregard of the emotional side of the character, thereby unfitting the woman for her natural vocation, that of motherhood and of caring for her children and home. While a few women succeed in competing with men on the same plane of mental endeavor the majority are more or less failures, their training on the lines of co-education, not having benefited them a jot, indeed rather the reverse.

Dr. G. Stanley Hall, the eminent American psychologist, has recently published a work on "Adolescence," a part of which treats of its relations to education. In a consideration of adolescent girls, and their education from a medical standpoint, the author quotes largely the opinions of medical men on the subject, some of which will be noticed here. Dr. Storer urged that girls should be educated far more in body and less in mind, and thought delicate girls frequently ruined in both body and mind by school. Dr. Clarke, in 1873, wrote a book in which he pleaded that woman's periods must be more respected. This work appeared at the height of the movement to secure collegiate opportunities for girls, and was suspected of being unofficially inspired by the unwillingness of Harvard University to receive them. It reached a seventeenth edition in a short time, but the views expressed therein were warmly combated by a number of ladies distinguished in the movement for the higher education of women. Clouston has, in various articles and books, expressed himself in very trenchant terms. In the United States, Clouston thinks that most families have more or less nervous taint or disease; that heredity is weak because woman has lost her cue, although nature is benign and always tends to a cure if we have not gone too far astray, but, he adds, "There is no time or place of organic repentance provided by nature for sins of the school master. A man can work if he is one-sided or defective, but not so a woman. "If she be not more or less finished and happy at twenty-five, she will never be." Parents want children to work in order to tone down their animal spirits, and it almost seems to Clouston as if the devil invented school for spite.

Dr. S. Weir Mitchell has so often given out his views on the question, that they are well-known. Woman, he holds, is physiologically other than man and no education can change her. Grant Allen said: "In any ideal community the greatest possible number of women must be devoted to maternity and marriage, and support by men must be assumed and not female celibacy. The accidental and exceptional must not be the rule or goal. This is only a *pis aller*. It is not so much the unmarried minority that need attention as the mothers. We must not abet woman as a sex in rebelling against ma-

ternity, quarrelling with the moon, or sacrificing wifehood to maidenhood."

Le Bon pleaded that the education we now give to girls consists of instruction that fits brains otherwise constructed, prevents womanly instincts, falsifies the spirit and judgment, enfeebles the constitution, confuses their moods concerning their duties and their happiness, and generally disequilibriates them. Sir James Crichton Browne holds that differences between sexes are involved in every organ and tissue, and deprecates the present relentless zeal of intersexual competition, concerning the results of which it is apalling to speculate from a medical point of view. When the University of St. Andrews opened its theological department to women, it was not a retrograde movement, because our ancestors did no such thing, but a downhill step fraught with confusion and disaster. He quotes with approval Huxley's phrase that "what has been decided among prehistoric protozoa cannot be annulled by act of Parliament." Prof. A. W. Small thinks that to train women to compete with men is like poison administered as a medicine, the evils being quite as bad as the disease.

So far as co-education is concerned, Dr. Stanley Hall thinks that while the system is not so harmful in college and still less harmful in university grades after the maturity which comes at eighteen or twenty has been achieved, it is high time to ask ourselves whether the theory and practice of identical co-education, especially in the high school, which has lately been carried to a greater extreme in this country than the rest of the world recognizes, has not brought certain grave dangers, and whether it does not interfere with the natural differentiations seen everywhere else.

The consensus of expert opinion is against the higher education of women carried to extremes, and particularly adverse to co-education. The weightiest argument against too much mental stimulus for women, is the fact that educated women, and especially highly educated women, are less fecund than their more ignorant sisters. Herbert Spencer was authority for the statement that "absolute or relative infertility is generally produced in women by mental labor carried to excess." According to Dr. Hall, this has probably been nowhere better illustrated than by college graduates. He says "Excessive intellectualism insidiously instils the same aversion to 'brute maternity' as does luxury, overindulgence, or excessive devotion to society. Just as a man must fight the battles of competition, and be ready to lay down his life for his country, so woman needs a heroism of her own to face the pain, danger, and work of bearing and rearing children, and whatever lowers the tone of her body, nerves, or morale so that she seeks to escape this function, merits the same kind of opprobrium which society metes out to the exempts who cannot or who will not fight to save their country in time of need."

The ordinary woman's true place is her home, and by far her most important duty to the race and to the State is the bearing and bringing up of children. Her educational training should at least not unfit her for the proper performance of this essential service. It is claimed, and undoubtedly with much truth, that the modern system of education does tend in this direction. Consequently, the system should be altered. If by a continuance of the present methods of educating women, the birth rate of those countries in which such methods are practised will inevitably decrease, it can be clearly understood that the game is not worth the candle.

DIAGNOSIS OF TOPHI IN THE EAR.

The differential diagnostic characters of tophi in the ears is discussed by Dr. Wilhelm Ebstein in a recent number of the *Deutsches Archiv fur klinische Medizin*. Strangely enough, there seems, the author tells us, to be no very accurate description of tophi in the books. The question is then under what circumstances one is justified in considering a nodule in the ear as referable to the group of tophi, and therefore proof of the existence of gout. The best description is that given by Garrod, who says tophi are sometimes single, sometimes numerous, sometimes smaller than a pin head, sometimes larger than a split pea. They generally have the appearance of pearls, and usually lie on the borders of the helix. As regards consistency they are sometimes hard and sandy, but frequently soft and yield a milky juice on puncture. Since Garrod's time little in the way of description of them seems to have been attempted. As to their significance, they are regarded as the exclusive property of the gouty. Thus Duckworth has found them in one-third of his cases (forty-nine out of 150), and as their appearance frequently precedes the arthritic manifestations of gout, their presence has acquired a diagnostic value that can hardly be overestimated.

In the course of the preceding year Ebstein has seen, in three cases, formations in the ears which resemble in many ways, and therefore require differentiation from the true gouty tophi, from which they are separated by the following characters: First, their seat is neither in the cuticle, nor in the subcutaneous connective tissue, but in the cartilaginous tissue itself; and, secondly, no uratic contents can be obtained from them. The first of the cases was that of a man, with gradually increasing joint pains, and old tuberculous lesions at the apices, who presented on the antihelix sharply bounded, hemispherical elevations, 4 mm. in diameter, with a hard feel, which yielded on puncture no fluid, the tumor being solid. The left knee-joint was 3 centimeters larger in circumference than the right, and the patellar bursa contained fluid which was drawn three times but never contained uric acid or urates. The second case, a man of thirty-two, developed the tophi-like bodies while under intermittent obervations extending over years. The helix and antihelix, tragus and antitragus, exhibited a series of prominences which, on puncture, yielded fluid not containing uric acid or urates. The mother was under treatment for chronic gouty arthritis. The third case was one of typical uratic gout, without typical tophi anywhere; prominences of cartilaginous consistence were present in the ear cartilage itself.

These observations, though few in number, nevertheless yielded a viewpoint that deserves attention. Grouped, the observations yield the result that rheumatic, and goutily-burdened individuals, tophi-like nodules may be present in the ears which do not correspond to the gouty deposits frequently occurring there, not being like the ordinary tophi, seated in the subcutaneous tissue, but lying in the cartilages

themselves. They appear to be generally of firm consistence, not deviating from that of the cartilage. Whether they bear a relation, and if so what relation, to rheumatism and gout, is an open question. This much, however, may at least be said, that in no case should one make a diagnosis of tophi, and therefrom of the presence of gout, unless he obtains uratic contents from the ear tumors.

MEMORIAL TO THE LATE MAYOR WALTER REED.

It is proposed to erect in the city of Washington, a suitable memorial to Walter Reed, Surgeon U. S. Army. For this purpose the Walter Reed Memorial Association has been formed and has further been incorporated under the general laws of the District of Columbia, to give unity to the various proposals which have been made for the securing of a Memorial Fund. The officers of the association are: *President*, D. C. Gilman, LL.D., *Vice-President*, General G. M. Sternberg, LL.D; *Treasurer*, Mr. Charles J. Bell; *Secretary*, General C. DeWill, U. S. A. The executive committee is composed of the following: Major I. R. Kean, Surgeon, U. S. A.; Major W. D. McCaw, Surgeon, U. S. A.; and Dr. A. F. U. King.

There are many and obvious reasons why the late Major Reed's memory should be perpetuated by the building of an appropriate monument. One reason is that physicians, whose benefits to the human race have been, perhaps, greater than those of any other profession, have been less often honored during life or after death than members of any other profession. Again, medical men of the United States have not been greatly distinguished in original scientific research, so that when an American surgeon has made a discovery such inestimable importance as the cause of yellow fever, it is fitting that the discoverer should receive every possible recognition.

Although Dr. Carlos Finlay of Havana, several years ago, had advanced the theory that a mosquito conveyed the yellow fever to man, he did not succeed in demonstrating the truth of his theory. It remained for Major Reed to prove fully by laboratory and practical experiments that such was indeed the case. The principal conclusions of the board of investigators, of which Reed was the leading spirit, were: (1) The specific agent in the causation of yellow fever exists in the blood of a patient for the first three days of his attack, after which time he ceased to be a menace to the health of others. (2) A mosquito of a single species, stegomyia fasciata, ingesting the blood of a patient during this infective period is powerless to convey the disease to another person by its bite until about twelve days have elapsed, but can do so thereafter for an indefinite period, probably during the remainder of its life. (3) The disease cannot in nature be spread in any other way than by the bite of the previously infected stegomyia articles used and soiled by patients who do not carry infection.

The application of methods suggested by these conclusions resulted in the virtual extirpation of the yellow fever in Havana, and like means may be relied upon to have correspondingly efficacious effects in localities in which yellow fever is rife.

It may be anticipated that it is but a matter of time when yellow fever will be known no more. That the discovery made by Reed is one of the first importance, must be clear to all. He was assuredly a benefactor to mankind at large, and as such his memory should be kept green. The medical profession throughout the country, military and civil alike, should haste to do honor to the name of Reed.

WORK OF THE PUBLIC HEALTH AND MARINE-HOSPITAL SERVICE.

The annual report of the Surgeon-General, recently issued, gives the doings of the Marine-hospital Service for the fiscal year 1903. A part of the report is devoted to the sanatorium for consumptives established by the service at Fort Stanton, New Mex. Two hundred and seventy-four patients have been treated at the sanatorium during the year, an excess of 62 over the previous year. There were 12 discharged, recovered; 54 discharged, improved; 10 discharged, not improved; 150 remained under treatment during the year. The treatment has been, on the whole, attended with very beneficial results, but as Surgeon P. M. Carrington, the surgeon in charge, remarks, patients leave too soon. He thinks that greater control should be exerted over the patients in this respect. It is therefore suggested that Congress be asked to pass a law which will enable the service to enlist these patients for, say, a period of one year, or to make other written agreement with them, with appropriate penalty for breach of contract on the part of the patient, granting authority to the commanding officer to arrest or otherwise restrain those desiring to leave without his consent prior to the termination of their enlistment or contract.

Regarding the plague, the report states that cases of this disease have continued to appear in the Chinese district of San Francisco, thirty-eight cases being reported during the fiscal year. The aid afforded the municipal authorities has been continued, and this joint work has no doubt served to confine the disease to its original limits. No case of yellow fever was reported in the United States during the fiscal year 1903, while Cuba has continued to be free from the disease.

During the fiscal year 857,046 immigrants were inspected by the officers of the service as to their physical fitness for admission, as prescribed by the immigration laws. One officer has been stationed at Naples, and another at Quebec, in the interest of the medical-inspection service. Examinations are conducted at thirty-two ports in the United States, and on account of the large number of immigrants entering at New York, Boston, Baltimore, Philadelphia, New Orleans, and San Francisco medical officers have been assigned to duty at these ports exclusively for the examination of arriving aliens.

At the close of the fiscal year the commissioned corps of the service consisted of 109 officers, as follows: The surgeon-general, 6 assistant surgeons-generals, 24 surgeons, 27 passed assistant surgeons, and 51 assistant surgeons. At the close of the fiscal year there were 179 acting assistant surgeons, including seven appointed for duty at fruit ports of Central America whose service will be terminated at the close of the quarantine season. During the fiscal year the scope of the hygienic laboratory has been increased with the additional features contemplated by the act of July 1, 1902. The Division of Zoology has been organized and the organization of the Division of Pharmacology is in progress. The Division of Chemistry will be organized at a later date. The work of the laboratory has been along lines pertaining to public health, examination of water supplies, a study of the action of various disinfectants and germicidal agents, the investigation of diseases and conditions of sanitary and economic importance.

Among the contributed articles in the report is an

excellent one by Passed Assistant Surgeon J. C. Perry on the epidemic of cholera in the Philippine Islands during 1902.

The Localization of Tabetic Lesions.

In the Paris letter of the *Albany Medical Annals*, for May, 1904, reference is made to Pierre Marie's article in the *Revue Neurologique* on this subject. Marie's article is probably the best exposition of the matter that has ever been given. The Paris school of neurology has made immense studies of late, and our knowledge of nervous pathology has been greatly increased by the laboratory work of men like Brissaud, Marie, Babinski, and others. The meeting of the "Société' Neurologique" on the first Thursday of every month is an event in scientific circles, for no meeting passes by without papers of the highest interest being read and earnestly discussed.

Marie, in his paper on "The Localization of Tabetic Lesions," proposed to explain this localization, by bringing into play the lymphatic distribution of the spinal meninges. He has noticed that in early tabes, the topography of the patches of sclerosis does not always coincide with the intramedullary course of the posterior nerve-roots, and therefore thought that this relationship was more apparent than real. For him the sclerosis of the posterior columns is not the extension of the process observed in the posterior nerve-roots, but is dependent upon, and limited by, the lymphatic supply. From the investigations of several observers and by laboratory experiments made by Marie himself and others, it is evident that the posterior columns, their meninges, and the posterior nerve-roots have a special lymphatic system, the "posterior lymphatic system," constituting in itself an anatomic entity, Marie consequently believes that the lesions of locomotor ataxia can be best explained by admitting that the morbid process is one of lymphatic origin and distribution. Marie ends his paper by saying that "The initial lesion of locomotor ataxia is a syphilitic lesion of the posterior spinal lymphatic system."

The primary cause of tabetic lesions has ever been of the greatest interest to the neurologist. Recently a certain amount of doubt has been cast upon the widely held belief that to syphilis must be attributed the origin of locomotor ataxia. The conclusions therefore of so eminent a student of nervous pathology as Marie cannot but carry much weight.

Military Sanitation in the Japanese Army.

The Japanese have afforded to a somewhat wondering world an excellent object lesson on the value of military organization and preparation for war. So well have they imitated and assimilated Western methods and ideas, that probably no European army is superior while more than one is inferior to that of Japan as regards equipment and organization. This is the case, too, with sanitary and medical affairs. The first evidence of the State of high efficiency to which the Japanese had brought their military medical organization was in the war with China in 1894. In the *Journal of the Association of Military Surgeons of the United States* for June, Lieutenant-Colonel John Van Rensselaer Hoff, Deputy Surgeon-General, U. S. A., calls attention to this almost forgotten fact. The writer quoted from writings of the present Director General of the British Royal Army Medical Corps, who was at the time of the Chino-Japanese war at the scene of conflict. The then Colonel Taylor says in part: "At Port Arthur there were opportunities of seeing how every part of the medical machine worked. . . . Lives were saved on the spot where the men fell, by the prompt application of tourniquet and even large arteries were ligatured under heavy fire. . . . The wounded were removed from the field without any delay just as quickly and quietly as they always were on the bi-weekly parades of the bearer columns in time of peace. If regiments were engaged far ahead, the regimental bearers did the work until the bearer companies came up, when they again took their places in the ranks. There was no loss of time, the medical men were everywhere."

So little news of the war has been allowed to leak out by the Japanese authorities that only the main facts are known. However, it may be taken for granted that the Japanese Military Medical Department has upheld the reputation it gained for itself in the war with China, and has successfully vied with the army in fulfilling its duties. There is no doubt that if the war with Russia is long protracted that there will be an immense amount of disease with which to deal. When the rainy season sets in, considering the insanitary state of the towns in Manchuria, typhoid fever will become rife, and it is not unlikely that plague and beriberi may attack the troops. Beriberi is a disease to which the Japanese are susceptible, and plague is a malady more prevalent in China than in any other country. The work before the medical organizations of both Russian and Japanese armies bids fair to tax their respective capabilities to the utmost, but, judging from the accounts of the Japanese Military medical service, it should, at least, be relied upon to cope with any situation presenting itself with credit.

News of the Week.

Medical Congress at St. Louis.—The plan and purpose of the Medical Department of the Congress of Arts and Science at St. Louis deviate so far from traditional lines that some explanation may be necessary to show how it should interest the medical profession. It is primarily a congress of scholars rather than of specialists. It is divided into twenty-four departments, one of the strongest of which is medicine. The Department of Medicine is divided into twelve sections, embracing the principal fields covered by the subject. These do not include Embryology, Anatomy, Physiology, or Bacteriology, as these subjects are embraced in in the Department of Biology. The Department of Medicine will be opened on Tuesday, September 20, under the chairmanship of Dr. William Osler, with two general addresses by Dr. W. T. Councilman of the Harvard Medical College and Dr. Frank Billings of the Rush Medical College. One of these speakers will review the progress of medicine during the past century, and the other will treat its fundamental conceptions.

On Wednesday morning, September 21, a section of Public Health will meet under the presidency of Dr. Walter Wyman, Surgeon-General of the U. S. Public Health and Marine-Hospital Service. It will be addressed by Prof. W. T. Sedgwick of the Massachusetts Institute of Technology and Dr. Ernst J. Lederle, formerly Commissioner of Health of New York City. Communications relating to the subject are also expected from several eminent members of the profession. A section of Otology and Laryngology will meet at the same time: Chairman, Dr. Glasgow of St. Louis; Principal Speakers, Sir Felix Semon of London and Dr. J. Solis-Cohen of Philadelphia.

In the afternoon a section of Preventive Medicine will meet, under the chairmanship of Dr. Mathews, President of the Kentucky Board of Health. It will be addressed by Professors Ronald Ross of Liverpool and Celli of Rome. Some question has been raised against the advisability of separating the sections of Preventive Medicine and Public Health. This separation is, however, of no practical importance, as all interested may equally well attend both. On the same afternoon a section of Pediatrics will meet under the chairmanship of Dr. Rotch, and will be addressed by Escherich of Vienna, Jacobi of New York, and others.

On Thursday morning, September 22, there will be meetings of sections of Pathology and Psychiatry. The chairmen of these sections are Drs. Simon Flexner and Edward Cowles respectively. Marchand of Leipzig and Orth of Berlin have accepted invitations to address the section of Pathology, but it is not certain whether both will be able to attend. Psychiatry will be treated by Ziehen of Berlin and Dana of New York.

In the afternoon a section of Neurology will meet, under the chairmanship of Prof. L. F. Barker of Chicago, and will be addressed by Kitasato of Tokio and Putnam of Boston.

The sections which will meet on Friday and Saturday, September 23 and 24, are as follows:

Therapeutics and Pharmacology. Chairman: Dr. Hobart A. Hare of Jefferson Medical College. Speakers: Sir Lauder Brunton, F.R.S., of London and Prof. Mathias E. O. Leibreich of the University of Berlin.

Internal Medicine, Friday afternoon. Chairman: Prof. F. C. Shattuck of Harvard University. Speakers: Prof. Clifford Allbutt, F.R.S., of the University of Cambridge and Prof. William S. Thayer of Johns Hopkins University.

Surgery, Friday morning. Chairman: Prof. Carl Beck of the Post-Graduate Medical School, New York. Speakers: Prof. Frederic S. Dennis of Cornell Medical College, New York, and one other not finally selected.

Gynecology, Saturday morning. Chairman: Prof. Howard A. Kelly of Johns Hopkins University. Speakers: Dr. L. Gustave Richelot, Member of the Academy of Medicine, Paris, and Prof. J. C. Webster of Rush Medical College, Chicago.

Ophthalmology, Saturday afternoon. Chairman: Dr. G. C. Harlan of Philadelphia, Pa. Speakers: Dr. Edward Jackson of Denver, Col., and Dr. George M. Gould of Philadelphia, Pa.

One of the two principal speakers in each section will treat of the relation of the subject to other departments of knowledge; and the other of its present problems. Besides the principal speakers it is expected that each section will receive several brief communications from leading members of the profession in attendance at the meeting. It will be seen that the division into sections is one of subjects rather than of men. The chairmen and speakers will be different in different sections, but the attendance, it is expected, will be the same, except in the sections holding their meetings at the same time

The California Medical Practice Law.—The Supreme Court of California has recently rendered a decision in a test case upholding the constitutionality of the law establishing the State Board of Medical Examiners. The decision not only declares the law constitutional in every respect, but approves of its object and affirms the need of such regulation of the practice of medicine in terms so emphatic as to effectually discourage all future attempts to evade the law.

University of Southern California.—The graduation exercises at the Medical Department of the University of Southern California, Los Angeles, were held on June 14. The degree was conferred upon twenty-four members of the class. A most enjoyable banquet was participated in by the faculty, graduating class and alumni, at the Angelus hotel in the evening. On the following Thursday the corner-stone of a new clinical laboratory building was laid. This is to be one of the best equipped laboratories in the West and will cost $200,000.

The Annual Sacrifice.—The *New York Times* says that the State Board of Health of Pennsylvania has communicated to the Mayors and Burgesses of every city and township in the State a memorandum calling attention to the need of a better enforcement of the law relative to the sale of toy-pistols and high explosives. It makes the assertion that the recorded casualties last year from the use of toy-pistols, giant firecrackers, and explosive toys during the Fourth of July celebration were 4,349 injuries and 466 deaths, or more than the Russian casualties in killed and wounded during the recent two days' fighting at Hai-Cheng. Its tabulated record of injuries and deaths last Fourth of July makes the following showing of totals:

Died of tetanus caused by injuries	406
Died of other injuries	60
Totally blinded	10
Number who lost one eye	75
Arms and legs lost	54
Number who lost fingers	174
Number injured who recovered	3,083
Total number of casualties in the United States	4,349

Warning against Yellow Fever.—Dr. Taber, the Commissioner of Health of Texas, has sent an official communication to the Governor requesting the latter to issue a proclamation warning the people of the State of the imminent danger of a yellow-fever epidemic if they neglect the first principles of cleanliness and sanitation in their houses and communities. On account of the open winter of 1903–4 in southern Texas and the prevalence of yellow fever in Mexico at present, he says he greatly fears that should a case be introduced into the State with the present very bad sanitary condition of a large number of the cities and towns and the presence of the yellow-fever mosquito, which also exists in large numbers throughout the State, there will be the most extensive epidemic of yellow fever ever known. He therefore urges the Governor "to issue a communication calling upon the county judges, mayors, and health officers of Texas to inaugurate sanitary campaigns in every community in the State without delay, especially for the destruction of the mosquitos."

The Manhattan Eye and Ear Hospital, which has been located for many years at Forty-first Street and Park Avenue, is to have a new home next door to the Baron Hirsch Trades School in East Sixty-third Street. The capacity of the present hospital is fifty ward patients, with eight rooms for private patients. It is proposed to construct eventually on the new plot buildings which will accommodate about four hundred ward patients and fifty private patients.

Exhibit of Johns Hopkins Hospital at the World's Fair.—The Johns Hopkins Hospital has placed a display in the Educational Building at the St. Louis Exposition. It is unique as being the only demonstration of nursing work among the exhibits. The exhibit consists of a series of photographs showing the hospital' exterior, views of the interior, groups of student nurses at work in the laboratories, class-rooms, and wards. Models of nursing appliances in operation, with specimens of charts,

etc., are intended to give an idea of the opportunities for nurses and the results of their training.

Sanitary Responsibility of Property Owners.—The Health Commissioner of St. Louis received a decision from the City Counselor in regard to the responsibility of agents, property owners, and tenants in cases in which insanitary conditions exist. The opinion of the Counselor states that an agent is never responsible except in cases in which he has power of attorney; that where more than one family occupy the premises, if the tenants are compelled to use toilet facilities in common, the owner should be held responsible; that if the premises are occupied by more than one family and there are separate toilet facilities for each family, the persons using these accommodations should be held responsible for their sanitary condition, be they owner or tenant.

An International Congress of House Sanitation.—The Société d'Hygiène Française has issued a call for an international congress to study the present hygienic conditions of dwellings and to devise means for their amelioration. The investigations and discussions of the congress will cover dwelling-houses in city and country, laborers' cottages and tenements, hotels, lodging houses, schools, and the living quarters on steam and sailing vessels. The work of the congress will be distributed among six sections, embracing the subjects above mentioned. The membership fee is fixed at 20 francs ($4). Those intending to present communications to the congress should forward the manuscript to the secretary-general not later than September 1. The President of the congress is Dr. Janssen; the Secretary-General, Dr. F. Marié Davy, 7 Rue Brézin, Paris.

First Toy-pistol Victim.—Walter Booth of Cincinnati was trephined June 25, at the City Hospital, for tetanus resulting from a toy-pistol wound. This is the first case in Cincinnati since the passage of the ordinance last March forbidding the sale of the toy-pistol.

Cocaine Habit in Cincinnati.—Despite the fact that stringent laws were passed by the Ohio Legislature last winter regulating the sale of cocaine, it is said that the sale of the drug in Cincinnati is larger now than ever before. It is sold principally on the levee and in the sections of the city where the dissolute congregate. It has been reliably estimated that 350 ounces of cocaine, of a value of about $6,000, is sold every month to this class in Cincinnati.

National Guard of Pennsylvania.—Dr. Joseph K. Weaver of Norristown has been promoted from Division Surgeon to Surgeon-General, replacing Dr. Robert G. LeConte of Philadelphia resigned. Dr. George H. Halberstadt of Pottsville has been reappointed Surgeon of the Third Brigade, and Dr. J. C. Biddle of Ashland has been appointed Assistant Surgeon of the Eighth Regiment.

Commencement Exercises of Rush Medical College.—This college, which is affiliated with the University of Chicago, held its commencement exercises June 15, at which time degrees were conferred on a class of 107. The Doctorate Address was delivered by Dr. Chas. G. Stockton of Buffalo, N. Y.

Increased Endowment.—The Chicago-Farmington Society held a lawn fête in Winnetka, Ill., recently, at which $2,000 was raised to complete the endowment of the Sarah Porter room in the Passavant Memorial Hospital.

Smallpox in Chicago.—Since the first of January there have been eighty-nine cases of this disease discovered in Chicago, and removed to the Isolation Hospital, and it is said of these not a single individual had been properly or recently vaccinated. Two patients died, seventy-six were discharged as recovered, and eleven were still under treatment.

Dr. John B. Murphy was recently elected President of the Chicago Medical Society

Hospital Needed.—Dr. Chas. E. Humiston of Austin, Ill., urges the establishment of a hospital at some point midway between Austin and Oak Park. The two villages have a population of fifty thousand, and the nearest hospital is four miles away.

New Hospital at Kewanee, Ill.—In the new St. Francis Hospital, Kewanee, organizations and individuals have already agreed to furnish twenty-one out of the twenty-four private rooms. Dr. L. A. Westgate has decided to sell or close the Sycamore Hospital, which has not been a profitable institution.

Physicians for Elks' Reunion.—Forty physicians have been appointed for service during the Elks' Reunion to take place in Cincinnati this week. They will serve without expense to the city, and will be uniformed in white with red crosses on sleeves.

Dr. Russell Hulbert.—The report recently published in the daily press and in these columns that Dr. Hulbert had escaped from a sanatorium at Green's Farms and walked to Higganum, was incorrect. Dr. Hulbert had left the sanatorium and was at his parents' house in Middletown. One day he walked from Durham to Higganum for the sake of exercise, and this was the only foundation for the report as published.

Pulmonary Diseases in the Street-sweepers of New York.—Street Cleaning Commissioner Woodbury made public a few days ago the result of his medical examination of the sweepers of the department. He was aided in this work by ten physicians of the Health Department. Out of a total of 1,872 men 283 were found to be afflicted with pulmonary complaints. Of this number only 60 had tuberculosis. The consumption scare in the Street Cleaning Department came about two months ago, when the department's doctors discovered that more than 25 per cent. of those who applied for sick leave were suffering from this disease. By the time the news reached the public it had taken growth, and the statements were made that a quarter of the entire street-cleaning force had consumption. The men became alarmed for their own safety, thinking that their work must be particularly dangerous, and their fears were not quieted by the discussion in the press of the peculiar dangers to which it was assumed they were exposed, despite the fresh-air theory of the prevention and cure of the disease.

Obituary Notes.—Dr George L. Fitch, a native of New York State and of late a resident of San Francisco, died suddenly at Santa Cruz, Calif., on June 2. From 1880 to 1885 Dr. Fitch served as the Crown physician of Hawaii. In this capacity he made a study of leprosy on Molokai.

Dr. Charles S. Woodward of thiscity died at Glens Falls on June 26, of pulmonary tuberculosis. He was born in Michigan thirty-five years ago, and was graduated from the New York University Medical School in the class of 1891. He was a member of the New York State Medical Association.

Dr. John F. Bird died at Fox Chase, Philadelphia, on June 23, at the age of eighty-nine years. He was graduated from the Medical Department of

the University of Pennsylvania in the class of 1843.

Dr. Julius J. Strecker died at Johnstown, Pa., on June 23 at the age of fifty-three years. He was graduated from Jefferson Medical College in the class of 1878. He was President of the Board of Health of Cambria County and Vice-President of the Cambria County Pharmaceutical Society.

Dr. Dennis J. Treacy died in Philadelphia on June 20 at the age of sixty years. He was graduated from Jefferson Medical College in the class of 1867.

Dr. James Simpson died in Philadelphia on June 20 at the age of sixty-five years. He was a student at Jefferson Medical College when the Civil War broke out, receiving appointment as an Army Surgeon and being placed in charge of the hospital corps at Alexandria, Va. At the close of the war he concluded his medical studies and was graduated from Jefferson College in the class of 1865. He was for several years chief physician to St. Mary's Hospital.

Dr. James M. Clement died of pneumonia in Philadelphia on June 12, at the age of seventy-one years. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1862.

Massage of the Heart for Chloroform Collapse.—W. W. Keen states that on only three occasions in his entire professional life has he had a patient die on the table. The first two were cases of operations on the brain and goiter respectively. Hemorrhage was the cause of death in both cases, all the usual means being unavailing. The third case was especially interesting for several reasons. This patient had previously had a fracture of the skull from which he had entirely recovered. He later suffered from squamous epithelioma of the vocal cords. At the first operation unilateral laryngectomy was performed, partly under local anæsthesia and partly under chloroform. The latter produced marked cyanosis. At the second operation, total laryngectomy was performed. Chloroform and oxygen were given to the patient, but not until he was upon the operating table. When enough chloroform was given to keep him quiet he became so cyanosed as to make the writer very anxious for his life. Just as the wound was ready to be closed his pulse suddenly failed and his face became suddenly blue. The operation and the administration of chloroform were immediately stopped. Strychnine was given hypodermically, pure oxygen was administered, and artificial respiration was instituted with rhythmical traction on the tongue. The battery was applied over the phrenic, but in spite of all this treatment, his heart continued to beat much faster and weaker; he became more cyanotic, and in two or three minutes he was dead. After continuing the above means for about ten minutes as a last resort the upper abdomen was opened and the writer introduced his hand into the abdominal cavity, and between this hand and the right hand, which made counter-pressure on the anterior wall of the chest, the heart was massed. These efforts were continued for nearly half an hour, but without avail. The writer then reports a case which came under Igelsrud's care. The operation was that of abdominal hysterectomy. There was chloroform collapse. The writer laid bare the heart by a resection of parts of the fourth and fifth ribs. The pericardium was opened and the heart seized between the thumb and fore and middle fingers on the anterior and posterior surfaces. Strong and rhythmical pressure was made for about one minute when the heart began to pulsate of itself, but as the pulsations became weaker, massage of the heart was practised for about one minute more. From that time the pulse was perceptible and the contractions of the heart became regular. The patient recovered. The writer gives an interesting *résumé* of work by various authorities on this subject.—*Proceedings of the Philadelphia County Medical Society*, March 31, 1904.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

HOSPITAL SUNDAY—SPONGE LEFT IN ABDOMEN, ACTION FOR DAMAGES—CENTRAL MIDWIVES' BOARD'S ABSURDITIES—DIRECTOR-GENERAL NAVAL MEDICAL DEPARTMENT—KING'S COLLEGE HOSPITAL—TUNBRIDGE WELLS HOSPITAL—NURSING ASSOCIATIONS—L. L. JENNER.

London, June 11, 1904.

We are on the eve of Hospital Sunday, and great efforts are being made to equal and, if possible, to surpass the last year's collection. That was the record year (£64,975). Some hope to make it £100,000 this year. Mr. George Herring has again promised to add one-fourth to the amount collected up to £100,000. Last year his cheque was £12,302. The *Lancet* has again issued a special supplement for distribution, and the Lord Mayor has made the usual appeal. Mr. Charles Morrison has sent in £1,000 to be added to the fund.

An action against a lady doctor was concluded on Tuesday in a way which seems fraught with serious consequences for the profession, while it controverts the received doctrine of negligence. A patient, on whom the doctor had performed an abdominal operation, brought the action for damages in consequence of a sponge having been left behind. The judge, in summing up, said there was no doubt that the operator was a skilful surgeon, but the question was not as to her skill but whether she had been guilty of want of reasonable care. He put the following questions to the jury: (1) Was the defendant guilty of want of due and reasonable care in respect of the counting or superintending the counting of the sponges? (2) Was the nurse employed to act as defendant's assistant during the operation? (3) Was the nurse guilty of negligence in counting? (4) Was the counting of the sponges a vital part of the operation? (5) Was the nurse under the control of the doctor during the operation? The jury after a long deliberation, answered all five questions in the affirmative and assessed the plaintiff's damages at one farthing. The judge pointed out that this was inconsistent with the findings on the other questions and the jury again retired to consider that point. On returning they said they did not think this was a case for damages, as the operation had been performed by the defendant without any fee. Finally, they declared plaintiff ought not to have more than £25, and that only in consideration of her suffering. Judgment was accordingly entered for that amount and costs.

Several questions are being talked about in reference to this case. It seems to traverse the general view that professional service is not to be accounted as negligent if ordinary skill and care be exercised. Special or expert skill is not the offer of the ordinary professional man. It is not improbable that much discussion on this point will take place.

Another question arises as to the liability of a doctor who renders a service without fee or reward. Should a patient who accepts gratuitous aid have a right to damages for unskilful or negligent treatment? If this is to be recognized as law, surgeons will become more chary of taking such cases, or may think it necessary to protect themselves by obtaining an indemnity beforehand, in case of a mischance occurring.

It would seem that those who leave counting sponges to the nurse are yet responsible for her errors—a decision which may serve to check the tendency to hand over to nurses duties for which they are not fitted. This applies to many points in practice. If a miscount by a nurse is to saddle the doctor with damages, the position becomes more serious.

Another point was raised in a conversation the other day, *viz.*, was the doctor in this case a member of one of the protection societies? Some said if not, she did not deserve pity. For ten shillings a year a kind of insurance can be entered into against the pecuniary consequences of such a misadventure. The defence would be undertaken by the society of which the doctor was a member, and would probably be more successful than when conducted by lawyers without special experience.

The last question reminds one that the annual meeting of the Defense Union was held on the 26th ult., when a very satisfactory report was presented. In the past year over 1,000 cases had been submitted for the council's consideration, besides many others which had been dealt with by the secretary. This shows the great risk that is run by practitioners in various ways. The cases that go to the solicitor are about 150 per annum. Some remarkable statements were made as to attempts at blackmail defeated by the intervention of the union, and of slanders or libels retracted and apologized for as soon

as the accusers found the defence was in the hands of a society.

The proposal of the British Medical Association to absorb the Defence Union was repudiated, and the meeting determined to "maintain the integrity of the union in its entirety as at present existing."

You know how the apathy of the profession allowed the Midwives' Act to pass—an apathy which many now lament. The Central Midwives' Board—the product of the act—has now resolved to invite reporters to its meetings. This is, so far, well, for hitherto the proceedings of the board have been characterized by ignorance and prejudice. So much so that Dr. W. J. Sinclair of Manchester, an independant member of the board has felt constrained to expose some of its doings. This eminent professor accepted a seat, but has not been able to secure the cooperation of the other medical members, and as a consequence the lay members have utterly ignored the profession—or rather, so far as they can, placed it in a position of inferiority to the midwives' calling. Thus, they have actually proposed to appoint a "trained woman" as an inspector of institutions applying for recognition. That such inspection would be useless, that it would be an insult to the medical staffs and, through them, to the whole profession to send a midwife to report on their teaching, was of no consequence. The midwife interest carried it—and that because three out of four medical members, to their shame be it said, declined to vote At the next meeting the degradation of the profession is to be carried a step further by a proposal to appoint matrons or midwives of lying-in hospitals as examiners.

Many county councils have appointed their medical officers of health as executive officers for the administration of the act. How will these M. O. H.'s, most of them highly qualified practitioners, relish the idea of their work being inspected by midwives or their teachings reported on by matrons?

You will remember how this board lately proved its incompetence by refusing to recognize the Dublin Schools of Obstetrics, which are notoriously the most efficient in these islands and perhaps in Europe. At the same time the London Obstetrical Society's diplomas were recognized as also a number of institutions with no pretense to be more than local lying-in charities But the board has now capped all its former exploits by a resolution that "it is desirable that Mrs. H—— should be certified, as it appears from her letter that she is quite prepared to take a case alone." This woman's letter stated "that she had not undertaken cases without doctors, but had been advised by a medical man that she need not be afraid to do so and she did not feel afraid of so acting." The resolution is in direct defiance of the board's own rules, and will serve as a precedent for any woman certifying herself as not afraid to act as a midwife.

All this scandal arises, as I have said, from the apathy of the mass of the profession and the readiness of a few men-midwives' to sacrifice the interests of their brethren to the "Midwives' Institute," a small trades-union of Mrs. Gamps.

Inspector-General Herbert M. Ellis, R. N., has been selected to succeed Inspector-General Sir H. F. Norbury, K.C.B., who will shortly retire, as Director General of the Navy Medical Department.

The Duke of Connaught has accepted the presidency of King's College Hospital in succession to the late Duke of Cambridge.

Last night there was a grand fancy ball at the Albert Hall on behalf of the removal fund. It was organized by the Countess of Pembroke, and a large number of the smart set attended and a great success was attained. The peculiarity proposed and largely carried out was for the ladies to adopt a fancy head-dress.

Tunbridge Wells Hospital has been enlarged at a cost of £25,000. The new buildings comprise male and female wards of twenty-four beds each, children's ward, isolation ward, and additional out-patients' accommodation. Ten thousand pounds has been raised and a bazaar was opened on Tuesday in aid of the fund.

The report of the Affiliated Benefit Nursing Associations for the Supply of Cottage Nurses, presented at the annual meeting on Wednesday, stated that 138 societies are now comprised in the organization, that the balance sheet is satisfactory, and that the demand for the benefits of the association is increasing.

The Colonial Nursing Association's annual meeting on Wednesday was graced by the presence of Princess Henry of Battenburg and a distinguished company. Mr Chamberlain was among them, and a reprint of his article in the *North-American Review* was distributed. This association has 109 nurses at work, 89 having been selected at the request of the government. Earl Grey said the association was filling the rôle and almost the dignity of a department of State and deserved the support of every public-spirited individual. The Duke of Marlborough added that the Colonial office constantly received evidence of its usefulness.

The first annual report of Lady Dudley's scheme to establish district nursing in the poorest parts of Ireland has just appeared, and in a rather attractive form. There are photographs of the districts where the nurses are at work. Nine nurses have been placed in cottages, or in lodgings in poverty-stricken places, and are doing a great work in ministering to the suffering poor. To extend the system only funds are needed, and for such help the committee appeals.

The death of Louis L. Jenner, M. B. Oxon., of the Lister Institute of Preventive Medicine, at the early age of thirty-eight, occurred on the 2d inst. He was the fourth son of the late Sir William Jenner, Bart., G.C.B.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

SANITARY PROBLEMS—NEED OF AN EFFICIENT PERSONNEL—LACK OF FUNDS—IGNORANCE OF THE NATIVES—OPPOSITION OF THE LANDLORDS—OUTLOOK PROMISING DESPITE OBSTACLES.

MANILA, May 26, 1904.

THE question of an efficient personnel for the execution of sanitary work is a very troublesome one. The number of available physicians is totally inadequate to meet medical and sanitary needs, and there are some four hundred municipalities in the islands having organized governments which have no local boards of health, for the reason that there is not a single physician or undergraduate in medicine living in any one of them. Clearly, without the advice of any medical man being available, any efforts at local sanitation in such towns must be inefficient, and proper statistics as to causes of mortality will be unobtainable. This deficiency in the number of medical men is one that can only be remedied by the education as physicians of a much larger number of young men than are now matriculating at the single medical school in the islands; the best that can be done to minimize the evil effects of such deficiency is to cause frequent inspections to be made of towns having no such boards of health by provincial and insular health officers. A higher standard of medical education should also be required. Not a few of the native physicians present marked professional deficiencies, not so much through their own fault as through the absence of modern facilities for their education. Manila is the only place in which there is a sufficiency of doctors, but there is no small difficulty in inducing these to take positions in the provinces, where they would be surrounded by a population regarding them with more or less distrust as foreigners and with whom they would have little that is congenial. For the minor sanitary positions there is less difficulty in securing satisfactory service, for the Filipino learns his part readily in the performance of routine and can carry out directions even when unable to initiate the proper action in an emergency. One trouble with this class of minor employees is that they are too apt to assume undue importance in their official positions and commit abuses liable to bring the whole sanitary service into disrepute. The employees of all grades, as a whole, require frequent inspection to keep them up to the efficient performance of a reasonable amount of work. In any medical emergency of any importance in the provinces, assistance and supplies must usually be sent to the local authorities from Manila, subject to the common annoying delays due to poor transportation facilities and deficient means of communication.

Another obstacle to health work is lack of funds. The proportion of the appropriations allotted to this purpose is satisfactory, but with the inception of sanitary work it was found that the investment of a vast amount of money in permanent sanitary improvements was necessary. Nothing of a sanitary nature was inherited from the Spaniards. In spite of the desire to limit outlay, many changes were imperatively demanded, and in Manila alone the attempt to convert it into a modern city, from one of the sixteenth century, in the brief space covered by the American occupation, would have bankrupted the inhabitants. Sanitary growth in other parts of the world is gradual, while here proper sanitation meant a complete remodeling of everything done up to that time. Tasks must be undertaken as a whole which in other countries would simply be continued over long terms of years. With a country left impoverished by war and pestilence, the revenues were naturally unsatisfactory and the appropriations for sanitary purposes suffered accordingly. The only remedy available is found in greater financial prosperity, and in the time necessary to accomplish the sanitary changes required.

Ignorance is a great bar to sanitary work. A large part of the population is illiterate, and some 600,000 of them

are savages. The amount of assistance in sanitary work which would be given by naked, head-hunting, and ghost-worshiping savages is naturally not great. It is useless to appeal to their intelligence and reason from the basis of modern medical science, for the latter is absolutely unknown to them and totally opposed to tribal teachings and customs. Even among the more intelligent Filipinos it is difficult to make many understand that sanitary science is based on accurate knowledge; they are unwilling to disinfect in cholera because they cannot see the bacilli, yet they pray for relief from the epidemic to an invisible San Roque. One great reason for ignorance on sanitary matters is the total absence in the past of any literature on the subject in the native languages, the lack of any such information in Spanish and the failure on the part of the Spaniards to give any instruction in such matters. Here a great opportunity is afforded for the inception of a sanitary educational propaganda, through the wide circulation of bulletins on health matters couched in simple language and printed in the various native tongues, and through the teaching of elementary hygiene throughout the public schools. Such an educational propaganda, efficiently conducted, should bring about more immediately satisfactory results than could be obtained in any other way, and is the best means of advancing sanitation at the present time. The board of health is already proceeding along these lines, both by the education of health officers in a practical school in Manila and the circulation of a vast amount of literature on health matters.

In Manila the chief objections to sanitary work now come from the wealthy householding class, who are unwilling to pay the bills for the sanitary remodeling of their unwholesome tenements. These bills have been very heavy, as naturally would be the case in a city where practically everything was wrong from a sanitary standpoint. This wealthy class has fought sanitary reform in every possible way, and has only lately come to the conclusion that compliance is necessary and that sanitary laws were made to be enforced. The poorer classes have lately come to understand that these sanitary reforms are much to their advantage and mean greater comforts and conveniences of life for them. A noticeable change has lately occurred in the much greater frequency with which these people are calling the attention of the sanitary authorities to unhygienic conditions, and requesting their abatement. The working classes are rapidly learning that health is their most valuable asset, and the householding class that an insanitary tenement is not a good investment.

On the whole, sanitary work here has every drawback met with in civilized communities, besides many obstacles of which the sanitary officer in the United States has no conception, and the importance of which can only be appreciated through extended personal experience. Nevertheless, the outlook for considerable sanitary progress in the early future is very promising. As far as the provinces go, sanitary advance must depend to a considerable extent upon commercial development and prosperity and the higher type of general civilization attached thereto. Ignorance and superstition are to be combated by education, racial dislike overcome, and distrust superseded by confidence. The guiding hand should be firm, yet diplomacy will be required and important sanitary problems can never be considered as apart from politics. The Filipino is readily susceptible to kindly handling, and a little tact and consideration will remove opposition that force could not brush aside. Many reforms cannot be carried out in an ideal manner; under such circumstances one must be contented with the best results which it is possible to obtain. Continued opposition along any given line is best met by temporary cessation of pressure until the people have become accustomed to the new order of things, when the advance may be resumed. Larger funds for sanitary expenditure will be available as the country recovers from the effects of war and epidemic, while experience will add to the efficiency of the sanitary personnel. Nevertheless, it is too much to expect that provincial conditions here will at any early date approach those of rural communities of the same size in the United States. With the exception of Japan, however, it is equally true that another decade should see provincial conditions here better than in any other part of the Orient. With regard to the city of Manila, sanitary improvement should be even more rapid. Much is now being done in the way of house repairs, grading, draining, filling, and the opening up of new means of communication. Work is shortly to be commenced on the new water supply, and it, with the drainage and sewerage systems already planned, should be completed within three or four years. Cholera has been banished, plague cut down, and special attention given to the infant mortality. The health work is constantly being broadened as opportunity offers and funds permit. In view of all this, there is no reason why Manila shall not share with Havana the honor of being the healthiest city in the tropics, and show a lesser mortality than many communities at home.

ELECTRICITY APPLIED TO THE DENUDED PERICARDIUM OVER THE VENTRICLE IN HEART FAILURE: A SUGGESTION.

To the Editor of the Medical Record:

Sir: As a possibly successful means of resuscitation in sudden heart-failure I would suggest laying bare the pericardium over the left ventricle and applying electricity at the bottom of the wound.

The usual failure of electricity applied over the præcordium to excite cardiac action is probably due in large part to the very great electrical resistance of the integument and the subcutaneous fascia characteristic of those structures. This resistance dissipates the current through a wide area, and necessitates such intensity of action as endangers deeper-lying nerve centers. With only the two layers of the pericardium between the electrode and the cardiac muscular fiber it should be easy, theoretically at least, to provoke contractions by a relatively feeble current, particularly if concentrated upon a limited area by the use of a small electrode.

Moreover, the possible importance of this power of limiting and controlling the action will be apparent when we consider the possibly disastrous effect of including the inhibitory nerves in the electric stimulation.

As a last resort, electric-puncture into the muscle substance might be tried, the surface of the heart being practically already exposed. Incidentally there would be an advantage in being able to note slight ventricular movements, of which there would be no indication if the chest-wall were intact.

THE PRESENT STATUS OF THE SURGICAL TREATMENT OF CHRONIC BRIGHT'S DISEASE.

To the Editor of the Medical Record.

Sir: An article bearing the above title, from the pen of Dr. A. A. Berg, which appears in the issue of your valued journal of June 18, has interested me. In this article the writer engages in the laudable attempt to base the indications for medical and surgical therapy upon the variety of nephritis present. For this purpose he arranges all cases of nephritis according to their etiology, under eight groups. As illustrating types of these groups, Dr. Berg details six cases; three of his own, two of Rovsing and one reported by the writer. A few not unimportant errors have crept into the report of the case last named; to correct these is the purpose of the present communication.

Dr. Berg writes: "As evidence of the bacterial infection producing different lesions in the kidneys of the same patient, the following history is quoted from Edebohls: In the one kidney are all the evidences of chronic Bright's disease, in the other multiple abscesses." Now, as a matter of fact as well as of record, both kidneys were the seat of chronic Bright's disease, and both kidneys were, in addition, affected by pyelonephritis with miliary abscesses.

Next follows an abstract of the history of my case as originally reported in full in the Medical Record of December 21, 1901. In the course of his abstract, Dr. Berg states: "After the operation (right nephrectomy), the patient's condition improved, and she gained flesh and strength, but her urine contained albumin and casts. *Gradual evidences of chronic Bright's disease developed and Edebohls performed decapsulation on the remaining kidney.*" This again is a misunderstanding on the part of Dr. Berg, possibly due to hurried or careless reading of my original report, where it is distinctly stated that the nephritis from the patient's last pregnancy, while infection of both kidneys occured only sometime after delivery. In other words, the case represented an instance of bilateral chronic parenchymatous nephritis with subsequent infection of both kidneys. The order of events was as follows: Chronic nephritis during entire last pregnancy, which terminated at term on February 12, 1901. Persistence of chronic nephritis after delivery. Hysterectomy for sloughing uterine fibroma, March 17, 1901. Acute proteus infection of right kidney a month later. Right nephrectomy for acute pyelonephritis with miliary abscesses, July 9, 1901. Persistence of left chronic nephritis and of pyuria. Decapsulation of left kidney, November 10, 1901.

While the above errors are perhaps explicable, I find it difficult to account for the following statement of Dr. Berg, on page 996: "Edebohls' case (cited above) of bilateral bacterial nephritis in which one kidney was removed and decapsulation performed upon the remaining one, was only temporarily improved, the patient finally succumbing to the disease." Not only has she *not* suc-

cumbed, but at the present writing, more than two years after decapsulation of the kidney, the patient is in the enjoyment of practically perfect health. This gratifying state of affairs has been reached after steady progress toward health during the past two years, a progress apparently continuous even at the present time. A trace of albumin, with a very occasional hyaline cast and leucocyte, are all the indications that remain of her former serious condition, while the patient has long ago resumed her duties in life, has absolutely no complaints of any kind, and considers herself a perfectly well woman.

I am possibly as deeply interested as any physician or surgeon in the solution of the problems of the surgical treatment of chronic Bright's disease. Articles of the scope and aims essayed by Dr. Berg are particularly welcome and appreciated, especially if based upon personal experience, as is the case in part at least in the present instance. So much keener is the disappointment when the validity of deductions and conclusions made and drawn are practically nullified by the incorrectness of the premises upon which they are based, and especially when such mistakes in the premises might, as in the instance before us, have been so readily avoided.

Whether other avoidable errors have crept into Dr. Berg's paper I am not prepared to say. Of unavoidable errors, that is, errors into which Dr. Berg's personal experience has perhaps not been sufficiently large or varied to prevent him from falling, I have noted one or two which I may attempt to correct in the proper place on a future occasion. GEORGE M. EDEBOHLS, M.D.

NEW YORK.

THE NATIONAL ASSOCIATION FOR THE STUDY AND PREVENTION OF TUBERCULOSIS.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR: I am in receipt of a number of inquiries from all over the United States and from abroad, concerning the outcome of the various meetings which have taken place in Baltimore, Philadelphia, New York, and Atlantic City in regard to the formation of a national tuberculosis association. Although your paper published a paragraph concerning the Atlantic City meeting, it must have escaped the notice of many of my correspondents.

The constitution and by-laws of an American National Association for the Study and Prevention of Tuberculosis were adopted on Monday, June 6, at Atlantic City. The objects of the organization, as stated in its constitution, are as follows: (*a*) The study of tuberculosis in all its forms and relations; (*b*) the dissemination of knowledge concerning the causes, treatment, and prevention of tuberculosis; (*c*) the encouragement of the prevention and scientific treatment of tuberculosis.

The following are the officers of this association: *President*, Dr. Edward L. Trudeau of Saranac Lake, N. Y.; *Vice-Presidents*, Dr. William Osler of Baltimore and Dr. Hermann M. Biggs of New York; *Treasurer*, Dr. George M. Sternberg of Washington, D. C.; *Secretary*, Dr. Henry Barton Jacobs of Baltimore. The Board of Directors, in addition to the officers above named, consists of Drs. Norman Bridge, S. E. Solly, John P. C. Foster, Arnold C. Klebs, Robert H. Babcock, J. N. Hurty, Wm. H. Welch, H. B. Jacobs, John S. Fulton, Henry M. Bracken, William Porter, Edward O. Otis, Vincent Y. Bowditch, Frederick L. Hoffman, S. A. Knopf, Edward T. Devine, Charles L. Minor, Charles O. Probst, Lawrence F. Flick, Mazyk P. Ravenel, H. S. Anders, Leonard Pearson, M. M. Smith, George E. Bushnell, and Walter Wyman.

Its membership is to consist of three classes: (*a*) Members—those who are elected by the Board of Directors and who pay annual membership dues of $5. (*b*) Life members—those who pay $200 and are already members of the association. (*c*) Honorary members—persons distinguished for original researches relating to tuberculosis, eminent as physicians or as philanthropists, who have given material aid in the study and prevention of tuberculosis.

The government of the association, the planning of work, the arrangement for meetings and congresses, and everything that appertains to legislation and direction, are to be in the hands of the Board of Directors, and committees are to have the power to execute only what is directed by the board. The Board of Directors is empowered, however, to appoint an executive committee of seven members to which is entrusted the executive work of the association. This committee, chosen at the meeting in Atlantic City, consists of Drs. Edward L. Trudeau, Henry Barton Jacobs, Edward O. Otis, Mazyk P. Ravenel, Arnold C. Klebs, John N. Hurty, and Mr. Edward T. Devine. The Board of Directors is empowered to appoint representatives to the International Committee on Tuberculosis. It was decided at the meeting of organization, that this representation was to be headed by Dr. Wm. Osler, and his associates will be selected later. The board is authorized, also, to appoint such committees as may be necessary for scientific and educational work, and for the holding of meetings and congresses.

The majority of the vast audience present at the Atlantic City meeting were enrolled as members of the new organization. S. A. KNOPF, M.D.

16 WEST NINETY-FIFTH STREET, NEW YORK.

THE POTASSIUM CHLORATE AND IRON MIXTURE.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR: Permit me to make a few remarks in connection with Dr. W. E. Dreyfus's brief article contained on page 1043 of the MEDICAL RECORD of June 25. While I regret that my name, or that of any other physician, should be linked together with any "special" prescription—that practice is always liable to tempt thoughtlessness and superficial routine—I admit that the doses published by the doctor are fairly correct. It will be noticed that a teaspoonful contains a grain of potassium chlorate and the double dose of the tincture of ferric chloride. When a dose is given every hour the amount taken in the course of a day amounts to about 16 or 18 grains of the salt. That is as it should be according to my teaching of the last forty-five years, in the case of a child of from two to six years of age. The same rules were given in the *American Medical Times* of 1860, in the second volume of Gerhardt's "Handbuch" (1876) and in my "Treatise on Diphtheria" (1880).

From the latter, which I happen to find on my shelves, I beg to quote what I could never sufficiently impress on colleagues or students: (Page 160) "The local effect cannot be obtained with occasional doses, but only by doses so frequently repeated that the remedy is in almost constant contact with the diseased surface. . . . It is better that the daily quantity of twenty grains should be given in fifty or sixty doses than in eight or ten; that is, the solution should be weak, and a drachm or half a drachm of such a solution may be given every hour or every half hour, or every fifteen or twenty minutes, care being taken that no water is given soon after the remedy has been administered for obvious reasons."

One of the main effects of the potassic chlorate is its preservative influence on the mucous membrane of the mouth, which should be kept as intact as possible to guard against the spreading of the membrane. From that point of view the recommendation to use the mixture in question as a gargle cannot be objected to. But (1) small children do not gargle, and (2) "gargles are not of much service" (in diphtheria) "for the simple reason that they do not come into immediate contact with the affected parts, and reach at the utmost to the anterior pillars of the soft palate" (page 192). I cannot help being delighted with my knowledge of the fact that this simple observation, probably not even original, and published by me first, forty-four years ago, has often been rediscovered and has given rise to numerous essays.

I have reason to believe that the composition as found in many drugstores is not always equal to that which is published by Dr. Dreyfus. The proportions given by him are, as I said, fairly correct. His chemical expositions are very gratifying. The individual physician will make such changes as will suit his case or cases. Very probably the next edition of the "Bellevue Hospital Formulary" will make appropriate alterations if the formula will ever be reprinted. I never knew it formed part of the formulary until lately. President Brannan was good enough to promise a revision at the proper time.

A. JACOBI, M.D.

BOLTON LANDING, LAKE GEORGE, N. Y., June 26, 1904.

The Blood in Malignant Disease.—Ernest Cunliffe, as the result of a year of fellowship work upon the blood in carcinoma and sarcoma, formulates the following conclusions: (1) There is a constant decrease in the hæmoglobin and hæmoglobin index. (2) The number of red cells is unaffected until the disease is advanced or the patient has suffered loss through hemorrhage. (3) Leucocytosis is the rule. It is caused especially by hemorrhage, metastasis, ulceration, and septic infection. It may be absent, however, throughout. Its sudden occurrence in such an instance indicates the probability of a metastasis. (4) The polymorphonuclear neutrophiles are increased in number. This feature may be present without the total number of leucocytes being raised, and in this relation points to the presence of malignancy. It is therefore a diagnostic sign of importance.—*Medical Chronicle.*

Progress of Medical Science.

The Boston Medical and Surgical Journal, June 23, 1904.

A Case of Labor in an Epileptic.—Annie Lee Hamilton gives the history of this interesting case. The patient was a primipara, twenty-six years of age. She had been subject to epileptic attacks for twelve years. She had sometimes had as many as two or three attacks in a week. During her pregnancy they were less frequent up to the sixth or seventh month, then rather more frequent between the seventh and eighth months. Up to December 8, four days previous to her entrance to the hospital, she had not had a convulsion for four weeks. On December 8 she had three, and two or three on each ensuing day until the eleventh, when she had five before coming to the hospital. She was now about eight and one-half months pregnant. She seemed to be in pain, and at first she resisted examination. The patient had two convulsions, and it was decided to dilate manually and deliver. There was no laceration. The patient soon apparently recovered from the ether but did not recover consciousness. The baby did very well for the first week but died within a few weeks of convulsions. The patient's condition for several days required very close watching. Finally, on December 18, she began to improve, and in talking, kept to the line of thought very well. On December 31 she was sent home, in very good condition. The treatment in the hospital was chiefly symptomatic. Elimination was carefully looked after and the nervous symptoms were treated by sodium bromide and hydrotherapy. Since her return home the convulsions have been decidedly less frequent. There seems to be very little in the literature in regard to this condition.

Medical News, June 25, 1904.

The Tracheal Traction Test as an Aid in the Recognition of the Asthmatic Lung.—Albert Abrams concludes that: When the head is thrown forcibly backward, the normal resonance obtained by percussion over the manubrium and lungs contiguous thereto, becomes converted into a dull or flat sound. This manœuver the writer has called the tracheal traction test. The tracheal traction test is positive in health and in all cardio-pulmonary affections, but it is negative in cases of idiopathic asthma. The recognition of this test affords a valuable aid in the diagnosis of idiopathic asthma, and assists in its differentiation from symptomatic asthma and other spasmodic pulmonary affections which suggest an asthmatic genesis. The manœuver specified as tracheal traction, evokes contraction of the bronchial muscle by stimulation of the pneumogastric nerves. In asthma the tone of the bronchial muscle is so reduced, that it no longer responds to vagus stimulation brought about when the neck is forcibly extended on the sternum; hence, the tracheal traction test in idiopathic asthma is negative.

Acute Thyroidism Following Curettage.—Brooks H. Wells reports a case of this nature. The patient, aged fifty-three, had passed the menopause at the usual time, but for the last six months had had repeated small bleedings from the uterus which was not enlarged and was freely movable. The patient for many years had had a slight enlargement of the right lobe of the thyroid, slight tremor, but no protrusion of the eyeballs. To exclude cancer of the fundus, a curettage of the uterus was performed. The scrapings showed only a moderate grade of endometritis. Six hours after the operation, the patient was flushed, tremulous, nervous and voluble, although her mind was clear. The pulse had risen to 130, and the temperature was 100.5° F. These symptoms increased in severity, excepting the temperature which fell. The thyroid was enlarged, especially on the right side, and presented quite an apparent thrill. There was marked throbbing of the heart and the large arteries. Examination of the urine revealed neither albumin nor casts. There were many colon bacilli, however, and a few pus-cells. These symptoms of extreme toxæmia continued to the end of the first week. On the tenth day the temperature reached 104.8° with a pulse of 148. There was no leucocytosis. Death was expected at any time from the fifteenth to the twenty-fourth day. The heart-action was most rapid and weak when the temperature was lowest. Diarrhœa ceased to be troublesome on the twenty-first day. On the twenty-fourth day the patient began to improve, and finally reached a condition approximating that before the operation.

Iodine and Mercury to Combat Local Infections.—Aug. Stabler describes a general method of treating local infections which has given him the most gratifying results in many cases of various kinds. The solution of iodine which he applies to mucous membranes, is as follows: A menstruum is made of equal parts of glycerin and water. To this is added tincture of iodine one drachm to the ounce, with a little belladonna and carbolic acid as local sedatives. This solution is applied through a simple hand atomizer to throat and nose, or to the uterus, vagina, urethra, or skin, in any way that is indicated. In using the atomizer, the patient holds the tube between the teeth with lips closed in the same position as in smoking a pipe, and breathes through the nose. The spray will come through the nose when the bulb is worked. Calomel is given internally in moderate doses, frequently repeated, and so mercuric iodide is formed in the system. In rheumatism this treatment achieves brilliant results. If used early, suppuration of the tonsil and joint and heart affections rarely occurs. In acute articular, the writer applies an iodine plaster to the affected joint. He also pushes the mercury internally, and gives a little acetanilid and salol. Subcutaneous affections, such as boils, felons, etc., are treated with the happiest results in this same way. The writer usually combines ichthyol and tincture of iodine, of each one part, with six parts boroglyceride. This is applied on lint or absorbent cotton, which is covered with parchment paper and a bandage.

New York Medical Journal, June 25, 1904.

Albuminuric Retinitis.—L. Webster Fox notes that the retinitis of Bright's disease occurs in about 30 per cent. of all cases of this malady, especially with the contracted kidney. It is nearly always bilateral, but may be unilateral. He describes the changes found in the acute and chronic forms respectively and refers to the accompanying blood changes. Vision is nearly always impaired or lost according to the number, extent, and situation of the hemorrhages. Prognosis as regards life is very grave. The treatment of the general condition will afford the best possible chances for improving the ocular area. The importance of the question of albuminuric retinitis lies in the necessity of making an early diagnosis, and the ability to do this is to a large extent denied the general practitioner, unless he has been trained in the use of the ophthalmoscope, as the symptoms, headache, and loss of vision are common to a number of less serious affections, and in the absence of expert advice on the subject such a patient might go wandering about aimlessly until too late to employ any measures which would be of any benefit whatever.

A Plea for a Truer Therapy—Real Treatment of the Sick.—Dr. W. C. Abbott refers to the fact that many physicians have lost faith in drugs and constantly prescribe empirically without a clear conception of what they wish to accomplish. In regard to dosage he notes that the effective dose depends on both the absorptive and eliminative powers of the patient. It must therefore constantly vary in both amount and frequency. There being absolutely no way by which we can determine *a priori* the amount of any drug which will produce the effect desired in any given case, it is left for us to find that dose by giving *to effect*—either remedial or physiological—beyond which we should not go. The only avenue of escape from therapeutic nihilism lies along the road of medication by active principles in small doses given to effect. Not alone by deduction is this the only rational therapy, but clinical experience with the active principles proves it absolutely. There can be no hesitation in adopting the active principles, if we admit the obvious fact that all medicinal action that a drug possesses is the result of the presence in that drug of one or more active principles. If of one, then does this active principle contain in itself a full expression of the therapeutics of the drug? If more than one active principle is present, then is it not better and more scientific, more exact, to study the action of each separately, than to give such empirically, hoping to get the desired results, which perhaps depend on the presence in *excess* of a certain alkaloid?

American Medicine, June 25, 1904.

Primary Typhoidal Cholecystitis, with Calculi.—Francis S. Stewart operated on the patient, whose case he reports. For three weeks before operation the woman, aged twenty-six, was intensely jaundiced. On admission to the hospital the temperature was 101° F., and the pulse 100. The blood coagulated in one minute. When the distended fundus of the gall-bladder was opened, there came out a small quantity of clear fluid and then a large quantity of sand and greenish-yellow pus. A stone about three-quarter inch in diameter was removed from the sacculation near the cystic duct. The pus from the gall-bladder gave a pure culture of bacillus typhosus. After this report was received, a test was made for the Widal reaction with positive results.

The Larynx in Beginning Pulmonary Tuberculosis.—W. G. B. Harland declares that examination of the larynx in all cases of tuberculosis can give important information. This may be positive or negative. In either case it will be of use in making a prognosis, and may give valuable

assistance in arriving at a diagnosis. Frequently, slight changes in the larynx are observed early in tuberculosis of the lungs. These changes may be congestive or anæmic. The writer declares that in the usual run of cases of beginning tuberculosis of the lungs, an examination of the larynx may give the first clue to the presence of the lung infection. When the larynx is the chief seat of the disease the diagnosis and prognosis must be founded on the local appearances present. In all cases the lesions observed in the larynx, as is true of those found elsewhere, will be of most value in making a diagnosis and prognosis when taken in connection with a thorough careful study of the case as a whole.

Three Points of Interest Concerning Smallpox and Vaccination.—Bernard Kohn reports three cases from which several conclusions may be easily deduced. The first patient, a girl of ten, although she had a physician's certificate of successful vaccination four or five years before, developed smallpox. No scars could be found on her arms. Several days later the girl's uncle developed the disease. He had been vaccinated several weeks before contracting the disease. It was doubtless a case of spurious vaccination due to poor virus. No vesicle was formed. A baby sister of the first patient, about seventeen months old, was vaccinated by the writer eight times, separate tubes of virus being used, the virus being very potent. None of them took, neither did the child contract smallpox, although she had countless opportunities for doing so. This must have been a rare case of natural immunity to smallpox and vaccinia also. The manufacture of vaccine virus should be more carefully supervised by the government. And more care should be exercised in the issuing of vaccination certificates and in admitting children to school on the strength of them.

The Lancet, June 18, 1904.

On the Etiology of Scurvy.—M. Coplans gives an extensive review of his personal experience with scurvy in the Transvaal and Orange River Colonies during the Boer war. He concludes that the disease is not due either to the presence or absence of any particular kind of food from the dietary but rather to an infection for which the food may act as a vehicle under conditions of impure storage or impure preparation. In his experience the disease prevailed in inverse proportion to the personal standard of hygiene, and this would seem to indicate that its infectivity depended on the insanitary habits and possibly the unwholesome occupations of those who were stricken with it.

Lymphatics of the Larynx and Malignant Disease.—P. de Santi discusses the anatomy of the laryngeal lymph channels and believes that these anatomical considerations have a direct bearing on the matters of choice of operation and prognosis. As regards the former the question turns on (1) the site of the origin of the disease and (2) the stage in which diagnosis is made. If an epithelioma of strictly intrinsic origin is seen and diagnosticated early while it is still limited, thyrotomy is amply sufficient to eradicate the disease. In the absence of obvious glandular involvement experience has shown that there is no need to perform a set operation to remove the group of glands liable to infection. On the other hand in most advanced cases of intrinsic cancer which necessitate removal of one-half of the larynx the corresponding glands ought to be removed whether they seem enlarged or not.

The Treatment of Tabes Dorsalis and Its Prognosis.—Maurice Faure notes that while certain cases of syphilitic tabes improve rapidly under vigorous mercurial treatment it is certain (1) that no tabetic gets well solely on account of the quantity of iodide or of mercury which he absorbs, and (2) that aggravation of the disease is more frequent among tabetics who are put on an antisyphilitic treatment in increasing doses than among those who are not treated in this way. It is necessary to avoid attributing exclusively to the action of heroic remedies, such as mercury, the relaxations and the diminutions in the symptoms of disease which are sometimes observed in the majority of cases of tabes, for such ameliorations are the rule, and it is incorrect to say that locomotor ataxia must be a disease which is necessarily and invariably progressive. The disease is steadily progressive in a third of the cases. It is arrested, improved, or gets well in about a fourth of the cases and in the remainder it proceeds very slowly with periods of quiescence only affecting the life of the patient seriously on occasions, and during the rest of his life offering him the possibility of living a life the activity of which doubtless must be diminished, but which is by no means very uncomfortable. As regards treatment, the best results will follow from care of the bladder, keeping the bowels open, attending to nutrition, providing against insomnia, compelling open-air life, preventing overwork, mental or physical, and by attending to the circulatory system

British Medical Journal, June 18, 1904.

Appendicular Colic.—W. Hesketh Evans describes one of his own cases in which, from time to time, appendicular colic was severe. There was no rise in temperature or alteration in pulse, but the pain became so severe that operation was performed. On cutting open the excised appendix, a dark-brown, semi-solid, foul-smelling substance oozed out. In the interior were several small pockets containing a similar substance with fecal odor. Large doses of opium would have probably masked the only symptom, and the termination might then have been fatal.

A Case of Leukanæmia.—F. Parkes Weber reports this case and sums up the main features as follows: Progressive waxy pallor and asthenia with maintenance of subcutaneous fat; changes in the red-blood corpuscles rather similar to, but not so extreme as, those met with in true pernicious anæmia; absence of true leukæmic changes in the blood, but presence of slight myelocythæmia and presence of the inverted proportion of lymphocytes to polymorphonuclears, which is found in cases of lymphatic pseudoleukæmia; no abnormal amount of pigment in the urine; changes found after death in the hæmopoietic tissues, similar to those which occur in cases of "mixed-cell" leukæmia, or pseudoleukæmia; abnormally firm consistence and increase of connective tissue in the bone-marrow from the shaft of a long bone; absence of enlargement of the ordinary lymph glands, but great hyperplasia of the spleen (hæmal gland) and prevertebral hæmolymph glands; absence of any reaction in sections of the spleen, liver, and kidneys for free iron, such as is found in pernicious anæmia. Charcot-Leyden crystals were not noticed in the bone-marrow, etc., but were not specially looked for. In spite of the poikilocytosis, the writer believes the disease in the present case to have been primary in the bone-marrow

The Deterioration of Vision During School Life.—Ettie Sayer has made a careful study of this subject. She has discovered that, at six years of age, 3 per cent. of school children have seriously bad vision, and 88 per cent. can see 6-6 with each eye. At eleven years of age, 11 per cent. have seriously bad vision, and only 58 per cent. see 6-6 with each eye. The rest have slight defects. The writer declares that no child's eyes were intended by nature to undergo the strain of accommodation for lessons, for six or seven hours every day of their lives, between four and fourteen years of age. But if compulsory education enforces it it becomes the duty of the Board of Education annually, to separate those 20,000 children or more, whose vision is so defective that they are unfit physically, to devise for them a specially modified curriculum, and to provide them with glasses if their parents are too poor or too ignorant, to do so. There is plenty of skilled manual work to be done by the class which is so poor that the public has to pay for their education, and they should be taught from their earliest infancy to regard this as their special lot in life. Not only the child with defective vision suffers, but also future generations. All eyes should be tested immediately on the child beginning its education, as to visual acuity; as to rapidity of perception; as to color blindness. At no time during school life should type smaller than pica be used. While infants should be allowed to use only chalk on cardboard. Reading should be learned from the blackboard. There is no defect more likely to be transmitted from parent to child, than that of defective eyesight.

Deutsche medizinische Wochenschrift, June 9, 1904.

Tuberculous Pericarditis.—Scagliosi reports an instance of this rare condition as occurring once in 1077 autopsies made at the University of Palermo. The patient was a woman of sixty who died as the result of a pyelonephritis. At the autopsy a moderate amount of serous fluid was found in the pericardium, and the inner layer was irregularly covered with small nodules, which were later on determined to be tuberculous. The lesion was proved to be primary in the pericardium, and the author thinks that the patient's age was the predisposing factor in determining this localization. It is well known that the blood-vessels of the heart in older persons are usually more or less diseased, and thus offer a point of lessened resistance. Careful histological examination of all the other organs and the lymphatic glands failed to reveal any traces of tuberculous processes. It seems rational to assume, therefore, that a primary tuberculous pericarditis may exist as a disease entity.

Rupture of a Tuberculous Abscess into the Trachea.—Gaudiani directs attention to the possibility of a destruction of the walls of the air passages by the softening of masses of tuberculous cervical lymph-nodes. This may be followed by a sudden invasion of the trachea and the bronchi, leading to death by asphyxiation. An instance of this comparatively rare condition is reported as having

occurred in a child of three, who had just recovered from what was supposed to be an angina. A few days later, sudden dyspnœa came on, and although a tracheotomy was done it was impossible to save the child. Autopsy showed that the trachea down to the bifurcation was surrounded by a mass of glands. A perforation had taken place and the bronchi were filled with cheesy masses. This case also shows the difficulties attending the proper diagnosis. The only differential point which distinguishes this from laryngeal stenosis is the character of this voice, which is but slightly affected in the former condition. No other symptoms may have been present to point to the extensive character of the diseased processes in the glands.

Treatment of Injuries to the Diaphragm.—Rona calls attention to the seriousness of this class of injuries, in which the proper surgical treatment is an urgent necessity. The patient, a boy of fifteen, presented a stab wound of the chest between the eighth and ninth ribs, through which a considerable portion of omentum protruded, pointing to an injury of both the pleura and the diaphragm. The transthoracic method of operation was employed, and after exposing the eighth rib under Schleich anæsthesia, a portion about 15 cm. long was resected. This disclosed a slit in the diaphragm about 4 cm. long, through which the omentum protruded. The latter was cut way after ligature and the stump dropped back into the abdomen. The upper border of the wound in the diaphragm was then sutured to the parietal peritoneum and the skin wound closed with the exception of the lower angle, in which a few strips of gauze were introduced for drainage. The patient made an uninterrupted recovery.

A New Property of the Tubercle Bacillus.—Piatkowski presents a preliminary communication dealing with the differentiation of the tubercle and the other acid-resisting bacilli. His method is based on the observation that the acid-resisting bacteria may be isolated from a mixture by diluting a small quantity of the latter with water or bouillon (10 c.c.) and then adding two to three drops of formalin. This is thoroughly shaken in a test-tube, and after half an hour a culture is made in a plain agar, or a glycerin-agar tube. Successive cultures are made from the same mixture at intervals of about fifteen minutes. In one or more of these tubes a pure culture of the bacillus will be found. It appears that the group of acid-resisting bacilli is less sensitive to the action of the diluted formalin solution than other varieties of bacteria. But even these are killed after prolonged exposure to the formalin, and so the difference is one of time only. The formalin solution has no effect whatever on the morphological characteristics of the acid-resisting bacilli and does not affect their staining properties. The author considers that this method can be more simplified, and is making further researches in this direction.

Berliner klinische Wochenschrift, June 9, 1904.

Gonorrhœal Phlebitis.—Heller reports an instance of this rather rare complication of gonorrhœa, a search of the literature disclosing the fact that this is only the twenty-sixth case on record. The patient presented neither varicose veins nor any other factor which could be considered as an etiological factor. About four weeks after a gonorrhœa, which had apparently subsided, he developed a marked phlebitis of the lesser saphenous veins and the pampiniform plexus, which gradually disappeared under appropriate treatment. The affection seems to be found most often in young men between the ages of twenty and thirty, and usually comes on during the first attack of gonorrhœa, during the subacute stage. An arthritis was present in most of the cases reported. A varicose condition of the veins was noted in but one instance, so that this cannot be looked upon as a predisposing factor. The veins of the lower extremity are involved in the large majority of cases, particularly the saphenous vein. The principal symptoms are pain and localized œdema, and the average duration of the disease is about six weeks. The prognosis is usually good, although a few fatal cases have been reported. The author considers that the process may be due to the rupture of some hidden focus, most likely prostatic, and the entrance of the septic material into the venous circulation. Treatment is that of phlebitis elsewhere.

Fatty Degeneration.—Rosenfeld thinks that this term should be limited to that condition in which an organ contains more fatty tissue than is normally present. This must be determined by chemical or microscopical methods. The latter, however, seems inadequate in most instances to afford any reliable quantitive estimate of the fat present in any given organ. Of the chemical methods, that which is based on the extraction by alcohol or chloroform seems most efficient. The author attempted to ascertain by experiments in animals which organs are the most liable to undergo a fatty degeneration. These were given phosphorus, phloridzin, chloroform, alcohol, and various other materials. The liver was apparently the most quickly affected. As regards the heart, chloroform and cantharides had no effect, alcohol and potassium bichromate caused an increase of about 2 per cent., phosphorus and phloridzin about 4 per cent., and extirpation of the pancreas was followed by an increase of 6 per cent. It seems, therefore, that there is no connection between the two in cases in which a patient dies from poisoning by chloroform and a fatty heart is found at autopsy. In the kidney a marked decrease in the amount of fat present is produced by cantharides and chloroform, very little change follows the administration of either phosphorus or potassium bichromate or extirpation of the pancreas, but a rather marked increase in the amount of fat is produced by alcohol. Muscular tissue, as a general thing, afforded the surprising picture of a diminution of the fatty elements rather than an increase. The author concludes from his observations that in those organs where fatty degeneration is present the fat arrives there by a process of migration.

Munchener medizinische Wochenschrift, June 7, 1904.

Treatment of Skin Diseases with the X-rays.—Muller reports on the employment of this agent in pruritus, hyperidrosis, and chronic eczema. By the use of moderately soft or even very soft tubes he obtained excellent results, but does not consider it wise to apply the method indiscriminately in these diseases without having tried other procedures. A case of pruritus vulvæ of long standing which had resisted other treatment was entirely cured after five exposures. In the case of profuse sweating of the hands, the exposures were followed by an exfoliation of the skin, and from the new dermal covering this excessive perspiration was absent. Another patient with this condition in the anal region was also favorably affected. The cases of chronic eczema were freed from the itching and the indurated skin after a few exposures.

Value of Lumbar Puncture in Meningitis.—Wertheimer believes that Quincke's method of lumbar puncture affords the means of offering a better prognosis in many cases of meningitis in children, especially in those instances in which this disease follows a pneumonia or acute infectious process, and in which the meningitis may with considerable certainty be considered of the serous type and free from bacteria. He claims that the therapeutic value is also considerable and believes that partial evacuation of the cerebrospinal canal should not be delayed until the test puncture has shown the presence of a high intracranial pressure. Rather it should be done as soon as the general symptoms, particularly the condition of the eyes, point to an increased cerebral pressure, and then the puncturing may be kept up until the pressure disappears. The author reports a case in which a meningitis followed a pneumonia, in which 560 c.c. of fluid werere moved from the spinal canal at intervals of several days. The fluid was proved free from bacteria. The symptoms subsided and the child made a good recovery.

French and Italian Journals.

A Case of Total Hysterical Deafness.—Bouyer has had under his care a case of total hysterical deafness which developed suddenly in consequence of a violent emotion. There is complete suppression of perception both by the medium of air and bone. The deafness has several times been momentarily suspended under the influence of certain therapeutic measures, which appeared to play especially a suggestive rôle—insufflation and electric treatment. The patient was able to preserve for several moments a normal perception, but soon the sounds became confused, and were lost in a distant murmur, which signalled the progressive return of the auditory nerve to numbness, and the development of intellectual torpor.—*Gazette Hebdomadaire des Sciences Médicales*, May 29, 1904.

Intestinal Occlusion by an Enormous Uterine Fibroma; Entire Relief of the Symptoms by Means of Right Lateral Decubitus.—Paul Gallois reports this case of a woman forty years of age, suffering from an enormous uterine fibroma. Constipation was persistent, the abdomen was distended, and the patient suffered from fever. Vomiting was also a troublesome symptom. The patient could not eat, and grew cachectic. The condition was growing alarming. It occurred to the writer to advise the patient to lie on her right side. He reasoned that this position would disengage the sigmoid flexure, and besides, it would throw the weight of the tumor on to the distended intestinal loops and increase their power of evacuation. Soon after the patient was able to lie on her right side gas escaped from the intestine, and fæces were quickly passed.—*Le Bulletin Médical*, May 28, 1904.

Hysterical Polydipsia and Polyuria of Eleven Years' Duration.—Sollier has observed a case of polydipsia and

polyuria in a young woman who drank from 12 to 17 litres of water daily with no complication of alcoholism. The polydipsia had been caused by a sensation of burning in the œsophagus, the effect of an acute hysterical attack which developed at the age of seventeen years. The burning sensation was relieved by drinking cold water. The polyuria, resulting from the polydipsia, persisted for eleven consecutive years, and then ceased, when the hysterical troubles were relieved. The patient was treated in a sanatorium by measures generally employed in hysteria—isolation, rest in bed, and mechanotherapy. Within three months, a complete cure resulted without the aid of any hypnotic suggestion of any kind.—*La Presse Médicale*, May 28, 1904.

A Large Foreign Body in the Nasal Fossæ.—Texier reports this unusual case of a man without morbid antecedents who was suffering with a suborbital fistula. There was a mucopurulent discharge from the nose. The fistula was thought to be due to a fall which had resulted in an abscess of the cheek. Two years before the patient's arm had been amputated as a result of injury by the explosion of a firearm. On examining the fistula, it was found that a probe could be pushed inward and backward for 12 cm. Rhinoscopic examination showed the presence of a foreign body which had gone through the septum, penetrating both nasal fossæ. It proved possible to seize the object through the fistula orifice and extract it. It was found to be a piece of iron about the size and length of the little finger. It had penetrated the nose at the time of the explosion, but the injury of the arm had been so severe that the accident to the nose had passed unnoticed.—*La Bulletin Médical*, May 18, 1904.

Results of Some New Researches on the Etiology of Rabies.—A. Negri states that in the nervous system of animals affected with hydrophobia is found a microorganism of the nature of a protozoon. It is found in the cells of the cerebrospinal axis. In dogs which have died of rabies furiosa after subdural injections of the virus, they are found in the encephalon, especially in the cornu ammonis. They are round, oval, or angular, when of large size. Many are smaller and round. They vary in size from 1 to 20 μ in diameter. The smaller ones are homogeneous, the large ones granular, irregular in shape, nucleated, with one or more nuclei. They may invade all the cells of the nervous system, the cells of Purkinjé, the cerebral cortex, pons, medulla, and Gasserian ganglion. In rabies paralytica the distribution is different; when inoculated in the sciatic, the disease is ascending, and attacks the cells of the spinal ganglia, and is not found in the brain. The author has found this organism in one case in man. They are soon destroyed by caustic alkali, but are not injured by acids. Drying, heat, putrefaction, glycerin, water, and physiological solutions do not affect their virulence.—*Lo Sperimentale*, April, 1904.

Movable Kidney and Enteroptosis.—H. Sérégé calls attention to the frequent coincidence of enteroptosis with the movable kidney. The latter condition is, in the great majority of cases, to be considered as one of the phenomena in the general process of splanchnoptosis. Gastrointestinal troubles in general, particularly those of infancy and adolescence, handing down a defective state of nutrition, are the origin of the process of ptosis in 54 per cent. of the cases. Pregnancy, alone, without other antecedent morbid cause, followed by serious dyspeptic troubles, appears to be the first cause in the proportion of 32 to 100. Multiplicity of pregnancies does not seem to augment the trouble to any sensible degree. Periodic congestion is noted as a cause. Traumatism is a rare cause. The treatment of the movable kidney, the writer believes to be essentially medical. As to surgical treatment, it should never be attempted till medical treatment has failed. The writer calls attention to the importance of the Glénard supporter. Besides this, he advocates the use of daily laxatives, the meat régime, and the use of alkalines. His results have been most encouraging. He believes in the use of the supporter even in cases in which the abdomen is not prominent.—*Journal de Médecine de Bordeaux*, May 29, 1904.

Four Conservative Cæsarean Sections and One Destructive One for Osteomalacia.—T. Morisani publishes five cases of cæsarean section done for pelvic deformities, three rachitic, two osteomalacic. The children were all saved. One mother died of sepsis. In one the uterus was removed, while in the others it was left. The author advocates making an incision in the median line of the fundus, from the highest portion, extending as far toward the symphysis as is necessary. The incision should avoid the location of the placenta as far as it can be ascertained, as this lessens the danger from hemorrhage. Hemorrhage depends less on the cutting of large vessels than on a lack of uterine contraction. In the median line of the uterus there are few large vessels to be cut. The extraction is also easier, and there is less danger of rupture of the uterus in a subsequent pregnancy because the scar is firmer. The higher up the incision, the stronger is the uterine muscle cut through. There is also less danger of ventral hernia, since the incision does not reach near the symphysis.—*Archivio di Ostetrica e Ginecologia*, March, 1904.

Comparison of the Agglutination of Different Tubercle Bacilli, in Relation to the Origin of the Bacilli and of the Serums.—M. S. Arloing and Paul Courmont conclude that: (1) Certain homogeneous cultures of tuberculosis are not agglutinable by tuberculous serums, even by serums obtained by inoculation of this same culture. The origin of the cultures does not seem to be the cause of the failure of agglutinability. They cannot serve for serum diagnosis. 2) The homogeneous cultures which are agglutinable, are so, whatever be their origin, in contrast to all the tuberculous agglutinating serums. The writers do not refer to the degree of agglutinating power. (3) Reciprocally, the experimental tuberculous serums, whatever may be the origin (human, bovine, or avian) of the infecting tuberculosis, are agglutinating for all the specimens of agglutinable tuberculosis. (4) Practically, the cultures of human tuberculosis are agglutinated by the serums of bovine tuberculosis and the cultures of bovine tuberculosis by the serums of human tuberculosis. The method of serum-diagnosis is then applicable to all kinds of tuberculosis, of whatever origin, on the condition of having a culture that is very agglutinable. (6) The study of agglutination does not allow of establishing very sensible differences between tuberculoses of different origin, especially between human and bovine tuberculosis.—*Lyon Médical*, April 24, 1904.

The Pathological Anatomy of Acute Delirium.—U. Alessi publishes the account of a case of acute delirium with pathological findings and some observations on the case. The patient, a man of thirty-five years, was of peaceful character, and had never indulged to excess in alcohol or tobacco. The onset of the disease was sudden, with acute mania of riches: he became loquacious, irritable and incoherent, unable to recognize his friends. This increased to excitement, motor irritability, insomnia, refusal of food, and a fever of 37° to 42°. This condition went on to extreme debility, coma, and death. A culture made from the blood showed the presence of pure cultures of pyogenes communis, which was also found in the brain. Examination of the cells of the brain showed marked degeneration of the cells, an acute parenchymatous degeneration of the fundamental nervous elements, *i.e.* an encephalitis. The author thinks that the title used for such affections should be based on the pathological conditions found, rather than on the clinical symptoms. Hence such a case should be called an acute parenchymatous encephalitis, rather than one of acute delirium. The cause of such an encephalitis may be a variety of organisms, as the bacillus of Bianchi-Piccinino, of Fraenkel, a streptococcus infection, or one due to pyogenes communis.—*La Riforma Medica*, April 27, 1904.

Rays and Emanations.—P. Schivardi compares the rays derived from the Crookes' tube and those of radium. He says that radium gives forth three sorts of rays: alpha, with slight power of penetration, arrested by aluminium; beta, with strong penetrating power, passing through lead; gamma, identical with the *x*-ray. A radium salt produces heat and light. Radium gives out positive, negative and *x*-rays, like the Crookes' tube, but spontaneously, and not as a result of outside stimulation. It seems to emit a sort of gas, as it were, which attaches itself to various bodies, and gives them radio-active powers; these are the emanations of radium. Another kind of rays come from the Crookes' tube called the *n*-rays, which are invisible, obscure, and yet traverse wood, metals, and the human body. They do not pass through lead or pure water. They do not act on the photographic plate, but they increase the luminosity of phosphoresent bodies, and make the light of a lamp more brilliant. They also increase the sensibility of the retina. These *n*-rays are a vibratory phenomenon of the ether, while the radium emanations are a liberation of a small amount of electricity, expelled from atoms of radio-active substances. A phosphorescent body is increased in brilliancy in the presence of muscular activity, in the neighborhood of the nerve trunks, or the central nervous system. There is a small instrument based on this principle, by which the course of the motor nerves can be followed out. This consists of a simple phosphorescent carbon disk. By means of it the topography of the central nervous system may be mapped out, as well as the psychomotor areas in the cerebral cortex, and the language centers. The human body also emits *n*-rays, increased in power by the functioning of the body. These emanations may serve to explain the phenomena of

telepathy and thought transference. Griffiths found radio-activity in the petals of odoriferous plants, such as the geranium. If a test instrument be placed over the speech center in the cortex, speaking will cause it to become luminous, especially in the presence of a low voice, while when silence supervenes the instrument becomes dark.—*Gazzetta Medica di Roma*, May 1, 1904.

Annals of Surgery, May, 1904.

Stricture of the Œsophagus Due to Typhoid Ulceration.—J. E. Thompson reports three personal cases and has found nine others on record, a résumé of which is given: Case 1 was somewhat relieved by dilatation measures, but finally died from inability to swallow. A similar treatment produced permanent relief in cases 2 and 3. As to the exact nature of œsophageal ulceration in typhoid, we have no definite information. Louis considered them as due not to typhoid infection but rather as a complication due to the extreme malnutrition of the tissues. It is very probable that the ulcers at the lower end of the gullet are due to peptic digestion of the œsophageal mucosa. The ulcers have been observed in many cases of exhausting and long-continued sicknesses. It is noteworthy that out of the twelve recorded cases, eleven occurred in males.

Rhinophyma.—W. W. Keen describes one case of rhinophyma resulting from an acne rosacea. In operating he excised the central portion of the growth from the upper margin of the diseased area down to the tip of the nose by an elliptical incision, the long axis of which corresponded to the bridge of the nose. H then sutured the edges. The pressure of the finger in suturing the lobules of tissue squeezed out from the ducts of the sebaceous glands a number of columns of sebaceous matter, commonly known as "worms." On the alæ of the nose, as it was impossible to obtain a suitable ellipse, he contented himself by simply shaving off all the hypertrophied tissue The hemorrhage was not severe; not a single vessel had to be ligated. A few clamps applied for a few minutes and the sutures checked the hemorrhage almost entirely, and a little adrenalin solution applied on the raw surface where he had shaved it completed the hæmostasis. Between the dressing and skin a bit of gutta-percha tissue was placed, so as to prevent adhesion of the dressing to the wound, which would retard the cicatrization. Recovery was rapid and complete.

Postoperative Pneumonia with Experiments upon Its Pathogeny.—The conclusions of W. L. Chapman are as follows: (1) Prophylaxis. Care in ether giving lessens shock and respiratory irritation, which reach their maximum when an unnecessarily large amount of ether is given. (2) The disinfection of the mouth and oropharynx by peroxide before operation is a rational precaution. (3) Adequate air space is of even greater importance in surgical wards than in medical. (4) A careful auscultation and percussion of the chest should precede every operation, and if there be signs of disease, operations of election should be postponed until the chest condition is more favorable. (5) A complete clinical record of all cases of postoperative pneumonia, together with a record of the previous state of the patient, is most desirable, and such records will in time greatly enrich our incomplete knowledge of the factors which predispose to the complication. (6) It is possible to demonstrate experimentally the lesions produced by suffocation and etherization, and the same philosophy which explains postoperative pneumonitis may be applied to that which occasionally follows poisoning by carbon monoxide and illuminating gas.

Lymphatic Constitution; Care of the Lymphatics During and After Surgical Operations.—F. Gwyer reminds us that infection is most commonly carried through the lymphatics, but that ordinarily the only care we take is to cut cleanly and not tear the tissues. We should exercise the same care in closing all lymphatic vessels and spaces as we do in occluding the blood-vessels. In operating on diseased glands he advises dissection to the point of exit of the vessel, which he then ligates as he would an artery or a vein. An additional value in his experience has arisen from the fact that the arterial supply enters at about the same point as the emergence of the lymphatic, and there has been less hemorrhage than otherwise. Ligation also facilitated the work, in that the vessels, lying usually toward the bottom of the wound, dissection is more difficult, and if bleeding occurs, it is more difficult to control; but if dissection is carried to that point and a ligature is thrown about the pedicle, as it were, much time is saved. In order to close up lymph spaces he rubs over the exposed area sterilized vaselin or iodoform-lanoline. In case of ordinary abscesses he incises, washes out the cavity, swabs it dry, and then fills it with one of the above preparations. The same plan is followed in the after-treatment of infected cases The ointment should be a soluble one. Hence bismuth, zinc oxide, and similar preparations are inadmissible.

Skin-grafting Infected Areas.—By "infected areas" S. F. Wilcox refers to raw surfaces which may or may not have been originally aseptic but which have become infected and from which pus exudes. To successfully skin-graft such areas we must first render them aseptic. The author thus describes his plan of doing this. The night before the operation the ulcerating and surrounding area should be cleansed as thoroughly as possible with green soap and hydrogen peroxide to remove the dried crusts and débris from the granulations. In case of very foul varicose ulcers, more time may be taken, and a compress wet with 50 per cent. solution of peroxide may be applied for a few days until the exudate is removed. After cleansing, the raw surface is covered with a compress saturated with a 1 per cent. solution of formaldehyde (the or inary 40 per cent. pharmaceutical preparation being the unit), and this compress is allowed to remain in place until the patient is on the operating table. When the compress is removed, it will be found that the granulation layer is dry and dark red in color, having an appearance much like smoked beef. This layer is about a quarter of an inch in depth; it is friable, and can easily be scraped off with a sharp spoon from the underlying tissue, which is whitish and bleeds very little. The removal of the granulation layer should be thorough, and what little oozing there is can be easily be stopped by the application of the Esmarch solid rubber band for a few minutes. The use of the rubber is a valuable step in the operation, as the smooth rubber makes equable compression and does not stick to the tissues when removed, but leaves an ideal surface for skin-grafting. The remainder of the operation is the ordinary one for the application of Thiersch's grafts. The after-treatment is the same.

Sialolithiasis.—According to O. T. Roberg, there are a few over two hundred cases of this condition on record. He describes one case occurring in a man of fifty-eight years who presented a condition leading to the diagnosis of calculus in Wharton's duct and probably in the submaxillary gland with suppuration of the latter and with suppurative cellulitis of the neck. An incision was made under local anæsthesia into the mass, and a small amount of thick, curdy pus escaped. One week later the swelling was considerally smaller and pus had ceased to discharge. The patient was then anæsthetized. The nodule in the mouth was incised, and by means of a small curette a concretion the size of a split pea was removed. An incision about three inches long was then made externally, parallel with the lower border of the jaw, and one-half inch below it. By means of blunt dissection through a mass of dense scar tissue the submaxillary gland was exposed and removed. The wound was packed with iodoform gauze, and only partly closed. A second calculus was found lodged in the beginning of the duct. Five weeks after the operation the wound was completely closed. After the operation there was paresis of the angle of the mouth, from which the patient had completely recovered four months later. Concerning the relation of bacteria to the formation of salivary calculi, the author believes that they cause a precipitation of the calcium salts by increasing the alkalinity of the saliva and removing the carbon dioxide. This explanation, however, does not account for the fact that calculi are found far more frequently in the submaxillary gland and duct than elsewhere.

Hæmoptysis.—In the treatment of hæmoptysis, Dr. W. von Bozoky does not approve of too much energy in this direction. The patient should be laid down with neck and chest freed from the pressure of clothing, and the upper portion of the body raised in order to facilitate expectoration. Then the patient should take deep breaths, which tend to restrain hemorrhage by inducing coagulation of blood and thrombus formation. Coughing should be checked, in order that the formation or development of a thrombus may be, as far as possible, promoted. Only a few slight coughs may be permitted, in order to get rid of the blood present in the upper air-passages. A morphine injection may be given with the view of calming the patient. The ice-bag may also have a favorable psychical influence. Ergot is not of much use; it tends to raise blood-pressure, and is not likely to be of avail in hæmoptysis. He does not approve of injections of gentian, which do not seem to have a favorable influence and are also attended by the risk of tetanus.—*Zeitschrift fur Tuberkulose und Heilstättenwesen.*

Book Reviews.

THE GAZETTE POCKET SPELLER AND DEFINER. English and Medical. Second Edition. New York: The Gazette Publishing Co., 1904.

THIS tiny volume of 216 pages is so compactly arranged that it can easily be slipped into any pocket. It is unusually comprehensive for its size. The words in the English section are briefly defined, mainly by synonyms. In the revision of this little volume nearly 700 English and more than 300 medical words have been added without increasing the size or number of pages. It is an extremely convenient little manual.

OBSTETRICS FOR NURSES. By JOSEPH B. DE LEE, M.D., Professor of Obstetrics, Northwestern University Medical School; Obstetrician to Mercy, Wesley, Provident, Cook County, and Chicago Lying-in Hospitals; Lecturer in the Nurses' Training Schools of same. Fully illustrated. Philadelphia, New York, London: W. B. Saunders & Company, 1904.

ALTHOUGH this book is intended by the author to be primarily for nurses, it is nevertheless, full of material valuable to the medical student, who frequently finds in his early years of obstetric practice the work of a nurse devolving upon him. Two main subjects are considered—obstetrics for nurses and the actual obstetric nursing. But the author has so skilfully combined them that the relations of one to the other are natural and helpful. This whole subject is one of such vital importance that a book of this kind, embodying as it does the experience of eight years of lecturing to the nurses of four different training schools, is most welcome to all those interested in obstetrics, whether nurses or physicians. The text is divided into three parts: Anatomy and Physiology of the Reproductive System, Nursing During Labor and in the Puerperium, and The Pathology of Pregnancy, Labor, and the Puerperium. There is an appendix treating of Visiting Nursing in Obstetric Practice, Hospital vs. Home Nursing. The Obstetric Nurse and Dietary. An excellent glossary and an index are appended. The illustrations, which are plentiful, are nearly all original, and were made expressly for this book. The author has taken the photographs from actual scenes, so that the details are true to life. We can warmly recommend this work.

MALADIES DES PAYS CHAUDS. Manuel de Pathologie Exotique. Par PATRICK MANSON. Traduit de l'Anglais par Maurice Guibaud, Médecin de la Marine, Jean Brengues, Médecin de l'Armée Coloniale, et Augmenté de Notes et d'un Appendice par M. Guibaud. Avec 114 illustrations et 2 planches en couleurs. Paris: C. Naud, 1904.

THE interest in tropical diseases has assumed such importance of recent years that a contribution to the subject like this comprehensive work now translated into the French language, is a most welcome addition to this branch of literature. In the introduction the author considers the etiology of tropical diseases. The book is divided into seven sections. In the first, various fevers are considered—malaria, yellow fever, bubonic plague dengue, Mediterranean fever, tropical typhoid, typho-malaria, sunstroke, unclassified fevers, etc. The second section treats of beriberi, epidemic dropsy, and the sleeping sickness. Then follow the abdominal affections—cholera, dysentery, diarrhœa, liver abscess, infantile biliary cirrhosis, etc. Leprosy, ulcerating granuloma of the genitals, and Oriental bubo are then discussed. Diseases due to animal parasites and associated maladies are accorded considerable space, and include such affections as lymphangitis, lymph scrotum, elephantiasis, bilharzia hæmatobia, endemic hæmaturia, craw-craw, trichocephalus dispar, ascaris lumbricoides, ankylostomum duodenale, strongylus, subtilis, tænia and nana, and bothriocephalus mansoni. The section on cutaneous diseases is divided into four parts, non-specific diseases, diseases due to bacteria, those due to vegetable parasites and those caused by animals. The last chapter deals with local maladies of an undetermined nature. One hundred and fourteen illustrations are scattered throughout the text. There are, besides, two colored plates.

A MANUAL OF HYGIENE AND SANITATION. By SENECA D. EGBERT, A.M., M.D., Professor of Hygiene and Dean of the Medico-Chirurgical College of Philadelphia; Member of the Academy of Natural Sciences of Philadelphia; Member of the American Medical Association. Third edition, enlarged and thoroughly revised. Illustrated with 86 engravings. Philadelphia and New York: Lea Brothers & Co., 1904.

THE third edition of this valuable book will receive a warm welcome from the many classes to whom it appeals. The treatment of the subject is so scientific and systematic that the book fills a want not well met by many other volumes on these topics. Since its appearance, five years ago, the text has increased by more than one-third of its original volume. The author has shown in the introductory chapters what practical hygiene and the employment of comparatively recent discoveries in this field are doing for the improvement of this country, the data being derived from the Reports of the United States Census of 1900. The writer calls attention to the fact that improvement of sanitary conditions within ten years has resulted in the lowering of the death rate for almost twenty-nine millions of people, for consumption, 24 per cent.; for typhoid fever, 27 per cent.; for diphtheria, 50 per cent.; and for malaria 54 per cent. The reduction of the general death rate for the same number of people means a saving of almost fifty-two thousand lives, as well as the prevention of an incalculable amount of sickness. The volume deals with personal as well as public health, and is an invaluable addition to the library, not only of the physician but also of the layman.

THE JOHNS HOPKINS HOSPITAL REPORTS. Volume XI. Baltimore: The Johns Hopkins Press, 1903.

THIS volume of the reports contains three monographs: (1) Pneumothorax: A Historical, Clinical, and Experimental Study, by Charles P. Emerson, A.B., M.D. (2) Clinical Observations on Blood-pressure, by Henry Wireman Cook, M.D., and John Bradford Briggs, M.D. (3) The Value of Tuberculin in Surgical Diagnosis, by Martin B. Tinker, M.D. The writer of "Pneumothorax" presents an exhaustive study of this subject. The first chapter gives a history of numerous cases reported by many different writers, going back to the earlier times. In later chapters the history, etiology, and pathology, with the clinical histories of cases, the mechanics of pneumothorax, the symptoms, course, prognosis, diagnosis, and treatment of the disease are discussed. The authors of "Clinical Observations on Blood-pressure," give the history of the principal methods of clinical sphygmomanometry; blood-pressure observations in surgical cases, in obstetrical cases, and in medical conditions. They finally treat of the comparative value of general stimulant measures. In the last paper, the value, dose, harmful use, injection, preparation and reliability of tuberculin in surgical diagnosis are discussed.

THE PRACTICAL CARE OF THE BABY. By THERON WENDELL KILMER, M.D., Associate Professor of Diseases of Children in the New York School of Clinical Medicine; Assistant Physician to the Out-patient Department of the Babies' Hospital, New York; Attending Physician to the Children's Department of the West Side German Dispensary, New York. With sixty-eight illustrations. Philadelphia: F. A. Davis Company, 1903.

THE author has presented his subject in a clear, concise, and interesting manner. He has gone into the explanation of details in a most painstaking fashion. The text is made very clear by numerous illustrations. The proper development, clothing, and feeding of the infant are all discussed. Then follow chapters on the diseases incident to babyhood. Finally, there are sections treating of the Nursery, the Wetnurse, Bad Habits, and Food Recipes. The text is so plain that the book cannot help but be of great value to mothers and nurses as well as to physicians.

A MANUAL OF CLINICAL DIAGNOSIS BY MEANS OF MICROSCOPICAL AND CHEMICAL METHODS. By CHAS. E. SIMON, M.D. Fifth Edition, revised and enlarged. New York and Philadelphia: Lea Brothers & Co., 1904.

SINCE its first appearance in 1896 this work has come to be regarded as one of the standards in this country in its particular field. The great strides made in this subject during recent years have necessitated frequent additions to the book in its successive editions, and the present one, the fifth, has attained the dimensions of a large octavo of almost 700 pages, with numerous illustrations. The purpose of the book is well stated in the author's preface, where it is said that exact methods of diagnosis necessarily underlie successful therapeusis, and should therefore be part of the equipment of every physician. Dr. Simon has at tempted to simplify the physician's work and to increase its efficiency by enabling him to eliminate doubt from his diagnosis. Besides a careful revision, this edition embodies much new matter which has appeared during the last few years. The section on the blood has been entirely rewritten and has been enlarged by sixty pages, especial pains having been taken with the chapter on technique. A section dealing with the nature of anilin dyes and the principles of staining has been introduced. For convenience of reference, the subject of leucocytosis has been arranged in such a manner that hyperleucocytosis and hypoleucocytosis are separately considered in connection with the different varieties of leucocytes. A new section deals with the cryoscopic examination of the blood. The chapters on the parasitology and bacteriology of the blood have been enlarged, with separate sections on paratyphoid fever, gonococcus septicæmia, bubonic plague, trypanosomiasis, and spotted fever. Many other additions and changes have also been made in other sections.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held May 19, 1904.

DR. VIRGIL P. GIBNEY, IN THE CHAIR.

The Distinctive Character of the Temperature Curve of Measles, and of Scarlet Fever—the Treatment of Hyperpyrexia in These Diseases.—Dr. H. W. BERG read this paper (see page 1).

Dr. HENRY KOPLIK said that the temperature curve during the enanthemata could not be considered exact as yet, because there had not been enough cases under observation to warrant any conclusion. During the enanthemata there would be apparently a slight rise of temperature, which might fall to normal, rise again and, in two or three days, would rise further with the appearance of the eruption. As to there being anything characteristic about the prodromal stage he hesitated to state; there was in all probability the temperature curve of an infection, same as would appear in an attack of tonsillitis or other infections. Even before the enanthemata there might be a slight rise, the child not being apparently well, running a temperature of one-half or one degree. There it was difficult to say when the temperature curve began or when it ended. With reference to the critical drop in measles he said that Dr. Berg was correct in the chart drawings, but there were uncomplicated cases which did not show this critical drop; in other words, all cases did not conform to this critical drop curve, because there were many cases recorded without any complications, so far as one could tell after the most careful and painstaking examinations, in which the temperature dropped by lysis. He could not, therefore, support Dr. Berg's assumption that uncomplicated cases of measles dropped by crisis. With regard to the statement of Dr. Berg that he had never seen a case of measles without temperature being present, he referred to a baby that was under observation for six days, and he did not know what the matter was. The baby was brought into the hospital with a slight bronchitis, and for a day it was watched carefully. The temperature was normal, being 99.4° by rectum. Soon the child broke out with an eruption, there was a conjunctivitis, the spots were well shown in the mouth, and the case proved to be one of well-developed measles. The baby was transferred to Riverside Hospital. Here was a well-marked case of measles without scarcely any pyrexia.

In regard to the scarlet fever temperature curve, he agreed with Dr. Berg that it acted as depicted by him in normal cases, but he said he had seen cases with temperatures of 103°, 104°, etc., which failed to drop, and when there were no complications. In these cases there was general enlargement of the lymphatic glands and a severe dermatitis. He remembered distinctly just such a case in which he was asked to point out the complication which kept up the fever; he looked for it everywhere but failed to find one. He thought it might be explained by the fact that the desquamation was so marked, and the glandular enlargement and toxæmia so marked that it kept the temperature running a week or two. He would endorse Dr. Berg so far as he had gone. There was nothing so typical as a scarlet fever normal curve, and nothing so varied as measles when the eruption was at its height to predict whether it would show a critical drop or not. There was another class of cases that had not been referred to in which there was no typical temperature curve at all, *i.e.* the malignant cases with temperatures remaining at 105°, 106°. To build a therapy upon the temperature curve he thought would be rather risky, for each case should be studied by itself. If left alone he believed the normal cases of measles would get well; at the same time, if the temperature remained up he did not hesitate to sponge them and adopt mild measures. He did not recommend cold sponging, but luke-warm water, as a rule. The more he saw of scarlet fever the less he felt that he knew of its treatment, and he believed that each case should be studied by itself. Lately he had seen a child, six years old, who was very ill with scarlet fever, and what helped this child more than anything else was placing him in the cold pack and then adding cold water; here no sponging was used. On the other hand, in private practice, he treated his cases of scarlet fever with sponging; some children bear cold sponging well with good reaction, and others bear warm sponging well. Again some children may go to pieces in a bath at 80°, but if the water was raised to 100° it would revive them.

Dr. ALEXANDER LAMBERT said that his experience coincided in the main with Dr. Berg's. Measles was associated with a distinct crisis, but the typical absolute crisis, as depicted on the charts, was the exception rather than the rule. When complications appeared, as a sudden attack of bronchitis, a temperature of 105° may be reached within thirty-six hours. He referred to one girl who had the typical rash, general adenitis, slight throat symptoms, etc. It was a very brilliant rash, and the case went on to complete desquamation at the end of six weeks, and at no time was the temperature above 99°. In another case there was the red and congested throat, the rash, adenitis, and a marked general desquamation and no temperature. He agreed with Dr. Koplik that in cases of scarlet fever, with very brilliant eruptions, in uncomplicated cases, the temperatures may run along for two or three weeks before coming to the normal.

Dr. WM. P. NORTHRUP said that measles, scarlet fever, and smallpox had exact charts, and related an instance in which he predicted what the chart would be in a child who contracted the disease from her sister who was suffering from scarlet fever. The thermometer should not be studied so much but the child's condition. He advocated the use of water inside and out, and said that the old adage, "keep the feet warm and the head cool," was a good one to follow.

Dr. Berg closed the discussion, and said that a great deal hinged upon the question of complications, and sometimes even the most astute clinician would overlook a complication. The question of irregular temperature curve at once raised the question as to the existence of complications. He was interested in what Dr. Koplik had stated regarding those cases which presented no temperatures in measles. He was very skeptical regarding such statements, because every case that he had noted showed a temperature rise of from one-half to one degree above the normal. With regard to scarlet-fever cases he had seen children playing and seemingly enjoying life when they had temperatures of 103.5°. He was skeptical regarding any acute eruptive disease going through its course without temperature. In reference to the malignant temperature curve of measles and scarlet fever he believed the word malignant brought at once before one's eyes the most toxic cases, and the high temperatures depended upon the septic manifestations, and these cases he did not include as being uncomplicated. By studying these curves he said he was able to look for complications which otherwise would have escaped his observation.

In regard to balneotherapy it was his custom to place the patient in a luke-warm bath at 80°, and raise the temperature about 10 degrees, thereby practically giving a warm bath after a cold one; by so doing he got rid of toxins, and the temperature would be lowered even further than if a bath at 60° had been given. He had seen temperature of 105° drop to 99.5° after one of these baths and stay there for nine or ten hours.

A Few Words Concerning Radium.—Dr. H. G. PIFFARD read this paper (see page 999, Vol. 65).

Dr. ROBERT ABBE said that he wished to express his opinion regarding this extraordinary agent, for he believed that there certainly was something in it; it was a very subtle agent, and was similar to the *x*-ray, the ultra-

violet, the Piffard, and Finsen rays. In its efficiency it lay between the *x*-ray and the Finsen light. Dr. Abbe then reported certain experiments that he had made showing the retarding effects of the radium upon the growth of seeds; the results were unquestionable. If twenty seeds were taken out that had been radiumized four days, and twenty more that had been subjected to its influence for two days, and twenty more that had not been radiumized, if these seeds were planted for ten days it would be shown that the seeds unradiumized would have grown seven inches, those that had been subjected to its influence for two days would have grown four inches, and those radiumized four days would have grown only two inches. The retarding influence upon these seeds as a result of the influence of radium was unquestionable. The same retarding effect was noted when the meal-worm was subjected to the influence of radium. Thousands of experiments had been made to show this *retarding influence* in both the vegetable and animal kingdom. Now if radium be laid upon the skin for a few hours it will produce a welt-like urticaria; the next day it will appear like a burn, and continue its effect, producing a dry necrosis, scaling off and leaving a scar with infiltration. A condition of necrosis and destruction of the tissue cells are produced. Under the microscope there will be found a leucocytosis, a thrombosis of the small blood-vessels, the nerves will be infiltrated, the leucocytes will infiltrate the tissues, all this excitation being produced by radium. Dr. Abbe had experimented upon himself and upon others. He found a suitable case for experimentation in the mammary gland which he was to amputate. There were two or three outlying nodes in the skin, and he allowed the radium on the skin for six hours on one place, then on another, etc., doing this for six days, when he had pathological lesions running over a period of six days. He then took a piece of radium and plunged it into the mammary growth, leaving it there for twenty-four hours, and then amputated the breast. The pathologist did the rest, and reported the following facts: For a distance of one-quarter of an inch there was a marked effect of the radium upon the tissues. The nest-cells had begun to be disorganized, and the superficial tissues of the skin necrosed. There was a vascular leucocyte infiltration which was very marked for one-quarter of an inch beneath in the mammary tissue, and at right angles to the line of section; there was a destructive necrosis of these nest-cells. The pathologist said he wanted tissue showing the influence of the radium for a longer period of time. He had another patient with cancer, and by the application of radium nineteen times in a period of three months he reduced its size one-third, and then cut out one of these cancerous nodules and gave it to the pathologist. Microscopically there was shown a fibrous infiltration and a reduction of the cancer cells, and the nest-cells were present, but much smaller in number. It was interesting to note that one could produce practically the same effect with a weak radium with longer applications, as with a strong radium with short applications. Dr. Abbe reported the case of a young man with a giant-celled sarcoma of the lower jaw. Six months ago the gums became swollen around the left lower canine tooth, which became loose. Four months ago he sought advice at St. Luke's Hospital. A soft spongy dark tumor occupied the lower jaw from the middle portion toward the left, and bulged inward under the tongue and outward under the skin. It was so soft that it seemed to fluctuate. It seemed to rise between the teeth. Three teeth were so loose that they could be lifted from the sockets. A radical operation was impossible without great deformity, and with a surety that the growth would recur; therefore he decided to try the influence of radium upon it, and this was applied over the growth within the teeth for one-half to one hour daily, a lead shield protecting the tongue. He next attacked the outer portion of the tumor by laying the tube between the lip and the tumor; this so blistered the mucous membrane that he decided to penetrate the tumor; he penetrated the tumor in its various parts, leaving the radium imbedded for two or three hours at a time. The growth was not only arrested, but there was an appreciable shrinkage in its bulk of about one-third its size. The boy to-day was in apparent perfect health. One week ago he took a trocar and removed a cylinder of tissue from the tumor, and examined it microscopically, and it still showed that it was a giant-celled sarcoma, but merely a shell. Dr. Abbe had the influence of the radium upon the seeds, and the meal-worms in his mind all the time, and he believed that he had greatly retarded the growth. This was a vast problem; he believed that, although the cells develop they can be held in check by radium, and he said what a tremendous contrast was presented in this patient with what would have happened if the growth had been unradiumized. Lupus and other conditions can be cured by radium, and those using this agent were having successes in various other conditions. A wart was a typical hypertrophy of one of the layers of the skin, and practically a tumor. He had a patient with warts upon both hands; on one hand he tried radium, and on the other monochloracetic acid; the warts disappeared from the hands at the same time. Radium had an extraordinary effect in producing a retrograde metamorphosis.

AMERICAN MEDICAL ASSOCIATION.

Fifty-fifth Annual Meeting, Held in Atlantic City, N. J., June 7, 8, 9, and 10, 1904.

(Special Report to the MEDICAL RECORD.)

(Continued from page 1065, Vol. 65.)

SECTION ON OBSTETRICS AND DISEASES OF WOMEN.

Third Day—Thursday, June 2, 1904.

The Surgical Treatment of Bilocular Uterus and Bifid Vagina.—Dr. H. W. LONGYEAR of Detroit referred to the meagre literature on this subject, and called attention to the fact that as the malformation was easy of correction, it should be operated upon as soon as discovered, so as to avoid the accidents of pregnancy and parturition which are liable to attend this anomaly of development. Before operating care was necessary in making a differential diagnosis between uterus duplex and uterus bicornis. The treatment recommended consisted in dividing the septum which separated the two uteri and vagina, and creating one cavity. The septum was grasped between clamps and cut with scissors, after which the Pacquelin cautery was applied to the cut edges, and the cavity packed with gauze. In the two cases which he reported, dysmenorrhœa was a marked symptom, but was relieved after operation, although in one of the cases an oophorectomy had to be done subsequently.

Dr. DUNNING of Indianapolis stated that he had seen two cases of bilocular uterus and vagina. During labor the septa were torn through. One was thin and offered little obstacle to the progress of the presenting part; the other was somewhat thicker. There was but light hemorrhage. Both cases did well, and he doubted whether an operation was necessary, as a general thing.

Dr. JOHNSON of Washington had seen a case in which, if operation had been done, much annoyance could have been avoided. The woman had been curetted for an apparent miscarriage and five months later was delivered of another fœtus. The condition was then found to be a double uterus with a pregnancy in each.

Dr. CARSTENS of Detroit reported two cases with septum which he divided, and although previously there had been miscarriages, full term pregnancy resulted. To prevent adhesions, he recommended the application of carbolic acid to the interior of the uterus after operation.

A Plea for More Thorough Examination of Doubtful Specimens of Ectopic Pregnancy.—Dr. J. W. BOVEE of Washington stated that many cases of ovarian and tubal hemor-

rhage have a symptomatology precisely similar to disturbed tubal or tuboovarian pregnancy, particularly tubal abortion. Specimens from such cases usually do not receive precise examination and are considered as pregnancy. For the sake of more reliable statistics, he thought that more careful histological examinations should be made. He reported ten cases in which the history indicated tubal pregnancy, but this diagnosis was not confirmed by microscopical examination. In two, malignant ovarian tumors were found.

Some Cases of Ectopic Gestation with Atypical Symptoms.—Dr. W. B. Dorsett of St. Louis called attention to the fact that many cases were occasionally found which did not present characteristic symptoms. Thus a right-sided tubal pregnancy might be mistaken for appendical inflammation. He had operated on forty-one cases with a mortality of six, and in some of these no diagnosis had been made, but other indications were present calling for surgical interference. He believed that the general condition of the patient should be made the guide for surgical intervention and not alone the history of the case.

Dr. Carstens of Detroit said that he had a case of supposed appendicitis, without fever or increased pulse rate, which turned out to have been a right-sided ectopic. He claimed that it was right to operate first and decide the pathology afterward.

Dr. Massey of Philadelphia entered a plea for more conservative measures in dealing with ectopic gestation, as in many cases nature had already begun the process of obsorbing the mass when operation was undertaken. He advocated the destruction of the fœtus by the electric current, where practicable, as an aid to this process.

Dr. Goldsohn of Chicago thought that the only difficulty lay in diagnosing the cases before rupture. In some cases microscopical evidence of the existence of a pregnancy could only be found in the cavity in the center of the blood-clot. He considered that the idea of the digestive function of the peritoneum was far-fetched.

Dr. Humiston of Cleveland said that after rupture he did not wait for subsidence of shock before undertaking operation, but after injecting saline solution under the breasts, he proceeded to carry it out immediately.

Dr. Dudley of New York considered that it was not necessary to remove the entire tube for non-septic conditions. After the fœtus was turned out, the ovary and tube could be dropped back, all occlusions, etc., having been corrected.

The Influence of Ovarian Implantation on Menstruation in Women.—Dr. A. P. Dudley of New York presented the following points for discussion: (1) Is the operation justifiable as a surgical procedure? (2) Is it worth the effort from a physiological standpoint? (3) Will the transplanted eventually resemble the fibroid in its action? (4) Is it possible that pregnancy may ultimately take place? (5) and provided it does, what is the prospect for normal delivery? Thus far he had done this operation in seven cases, all of which subsequently menstruated but at irregular intervals, and no physiological changes or nervous manifestations resulted. One of his last cases he reported in full. The patient had had both tubes and one ovary removed, and for the relief of her symptoms, hysterectomy had been advised, but to which she would not consent. Operation was undertaken and the ovary freed from its adhesions, but left attached by the ovarian ligament, was implanted directly in the uterine cavity in a space previously gauged out in the muscular substance. Primary union resulted and the woman menstruated three months after the operation, and then, at intervals, every three months. Eighteen months later she developed a severe menorrhagia, and hysterectomy had finally to be done three years after the first operation. Examination showed that the ovarian and uterine tissues had become merged, with Graafian follicles present. He was at a loss to account for the hemorrhages. The specimens obtained from this case were presented at the meeting. The reader doubted the extended applicability of the method, but believed that it might be advantageously employed in isolated cases.

A Plea for Conservative Operations on the Ovaries, from a Neurotic Standpoint, with a Report of Cases.—Dr. J. W. Cokenower of Des Moines read this paper, in which he called attention to the necessity of making a better diagnosis in those cases in which the symptoms presented were ascribed to ovarian disorders. In many instances it was questionable whether the trouble was really due to the ovary. It was much more likely to be an intoxication traceable to the intestinal canal, of which the pelvic disease was the result, rather than the cause. Neurotic cases were rare in which the symptoms were wholly dependent on the sexual organs. It was important to recognize when to conclude medical treatment and institute surgical measures. The consensus of opinion of many observers rather than the statistical reports of a few, should be given preference. Negative results for conservative ovarian operations for the relief of neurotic conditions were common, and between the two extreme views as to the advisability of operating, an intermediate view was the best. He reported four cases in which single or double oophorectomy and hysterectomy had been done, with disappointing results. He thought that in many cases we operated when we should not have done so.

Dr. Morris of New York opened the discussion on Dr. Dudley's paper. He discussed the advantages of the procedure and the respective value of homoplastic and heteroplastic transplantation. He had made numerous experiments on rabbits, and the latter method was unsuccessful. He thought that it was well to save the ovary in a case of pyosalpinx, and he found that the organs could be kept in hot saline solution for several hours without injury, before being transplanted and while the remaining operative procedures were being completed. In discussing Dr. Cokenower's paper, he called attention to the fact that it was essential to carefully differentiate fundamental psychoses from neuroses.

Dr. Goldspohn of Chicago opened the discussion of Dr. Cokenower's paper. He thought the question might be solved by distinguishing between psychical and actual pain. Every other part of the body should be examined before the pelvis. He had also invariably found that pelvic lesions were aggravated by the erect posture or anything else that favored congestion.

Dr. Humiston of Cleveland found that frequently the pelvic organs were normal and other organs accounted for the neuroses. In discussing operative measures, he stated that he only attained good results from the complete operations.

Dr. Bacon of Chicago thought that the site of implantation was not favorable, as the implanted ovary might be washed away by the uterine discharges. He believed that the chief object was to secure the advantages of internal ovarian secretion, rather than the possibilities of pregnancy.

Dr. Massey of Philadelphia considered that in many cases it was necessary to remove the inflammation rather than the organ itself, and in this connection he believed that kataphoresis with the mercuric ions valuable.

Dr. Carstens of Detroit thought that occasionally in young women a favorable case for the Dudley operation might be found, but that in older women it was best to remove the ovaries if the symptoms were bad.

Dr. Craig of Boston had observed that the normal ovary became scarred during middle life from cicatrization of the continually rupturing Graafian follicles, and that many so-called cystic ovaries, without clinical symptoms, contained merely enlarged Graafian follicles. As it was an essential thing to keep up the internal ovarian secretion, he believed that under the proper circumstances, Dudley's operation was favorable.

Dr. Chandler of Philadelphia thought that Dudley's

operation presented many advantages and but few objections. Among the latter were the remote possibility of sepsis, the death of the ovary, the production of malignancy, and the action on the fœtus. The main advantage he considered to be the postponement of the menopause.

A Series of Mistaken Gynecological Diagnosis.—Dr. T. S. Cullen of Baltimore reported the following interesting cases: (1) Was diagnosed as a large multilocular ovarian cyst, which at operation was found to be a pedunculated fibroid, partially parasitic The omentum was markedly atrophied and ascites was present. The latter is extremely rare with fibroid conditions. (2) Here the uterus was enlarged, globular, with apparently two subperitoneal nodules. On account of the general history no examination of scrapings was thought necessary. At operation an advanced adenocarcinoma of the corpus was found. (3) Here a globular mass projected from the right side of the uterus and from the vicinity of the right cornu a subperitoneal nodule. Both uterus and nodules were movable and a diagnosis of intraligamentous and subperitoneal myomata made. At operation the subperitoneal nodule proved to be a tense and kinked hydrosalpinx, the intraligamentary growth an adenocarcinoma of the ovary invading the bladder wall. (4) This patient, aged sixty, presented temperatures from 100 to 103°. There was marked pain in the pelvis and slight discomfort in defecation. In the vaginal vault, and apparently attached to the posterior surface of the uterus, was a slightly irregular but globular mass. The diagnosis was between adhesions of subperitoneal myoma glued to the pelvic floor and pelvic abscess. Operation showed an irregular globular tumor involving the sigmoid flexure. This had dropped over to the right side and become adherent to the pelvic floor. Diverticulæ were filled with fecal concretions, and between the floor and the growth was a small abscess due to rupture of a diverticulum from the intestine. The tumor was benign. (5) A case of adenocarcinoma of the kidney had been well for sixteen months after operation. Then a rapidly growing tumor was noticed in the hepatic region, which turned out to be a neoplasm involving the lower half of the liver, but was not a metastatic growth.

Injury to the Rectum in Gynecological Examinations.—Dr. H. A. Kelly of Baltimore called attention to the importance of the rectum as an avenue of investigation and the obstacles encountered by this route. A rough examination might readily rupture cystic structures and spread their contents over the abdomen. He had also seen several cases in which the finger was pushed through the rectum and entered the abdominal cavity, necessitating repair by laparotomy. In one instance it was found that a large ovarian cyst had been punctured. The accident depended not so much on the rough handling or carelessness of the examiner, as on the soft and friable character of these tissues. In making a rectal examination, it was always well to recognize, but not to invaginate the ampullæ and to get the finger beyond what might be called the third sphincter of the rectum. During an examination it was most essential that the arm be perfectly relaxed, and the wrist not held stiffly. Distending the bowel with air also greatly facilitated the examination. When injured, the rectum might be repaired through the posterior cul-de-sac, or, if advisable, by the abdominal route. He asked that cases of this kind be put on record.

Dr. Wetherill of Denver called attention to the possibility of injuring the rectum during the conduct of a labor, when the operator's finger was inserted into the rectum to support the advancing fetal head. Dr. Cullen of Baltimore reported two cases in which the rectum had been injured. Dr. Shoemaker of Philadelphia mentioned an instance in which an appendical abscess had been ruptured by the hydrostatic pressure of an enema, and Dr. Noble of Philadelphia also reported a case of pelvic abscess ruptured by rectal examination.

Some Further Observations on the Use of the Stem Pessary for Scanty and Painful Menstruation.—Dr. J. H Carstens of Detroit stated that in a certain class of cases these conditions could only be ascribed to lack of exercise of the uterine muscle. He thought that the organ could be sufficiently well developed by the introduction of a foreign body which the uterus would constantly endeavor to expel. In another class of cases, dysmenorrhœa comes on later, after normal menstruation for years, in which the uterus, and especially the cervix, had undergone premature atrophy. All these cases might be relieved by the introduction of a stem pessary. In one of his cases the stem had been in place for two years, but after removal a gradual return of her symptoms took place, which was finally relieved by the reintroduction of the instrument. In another case of sterility of five years' standing, pregnancy came on after the use of the stem for a few months.

The Propriety, Indications, and Methods for the Termination of Pregnancy.—Dr. F. A. Higgins of Boston believed that there were evidences of broadening of the indications for the termination of pregnancy, and the wisdom of this could not be questioned. The question remained whether this would lead to ill-advised abortion, but he felt safe in stating that he did not think it would. He discussed in detail the influences exerted by the various acute and chronic diseases. An acute disease was not usually an indication, but if labor comes on, it should be hastened. The religious question was also touched upon.

As for the methods, he considered bougies favorable in certain cases, but thought it better to employ two than one. He recommended, however, the Vorhees bag and the colpeurynter. Manual dilatation was accompanied by the danger of rupture. Instruments, he claimed, were under more complete control, and therefore more secure. The dilatation in each case depends on the amount of stretching which the cervix will endure. The Bossi dilator was shown and discussed, and the author's newly modified instrument presented. This was more compact than the Bossi and claimed to be less dangerous. It might also be used for dilating the cervix before ordinary curettage.

Dr. Hall of Kansas City said that he thought it was more honorable to suggest methods of preventing pregnancy in questionable cases rather than to devise methods of abortion. He believed that the effect of such a paper might be bad on the public mind. Where the necessity existed, he considered that the instrument was preferable to the use of the fingers.

Dr. Bacon of Chicago claimed that the social condition of the patient should be largely taken into account in deciding the advisability of abortion. In the case of hydramnion and twins, he advised rupture of the membranes, and the bag, when used, should then be placed within the egg sac. In his opinion, vaginal cæsarean section was to be preferred to the use of instruments.

Adherent Uterus as a Complication of Labor.—Dr. J. C. Applegate of Philadelphia discussed the circumstances under which the pregnant woman with adherent uterus should be allowed to go to full term, and the best method by which such complications could be treated. He found that the round ligament suspensory operations had no effect, but that labor quite fully destroyed the results of the previous operation. Peritoneal suspension was dangerous from possible rupture of the uterus. Ventral fixation was unjustifiable before the menopause, except under rare circumstances. Before attempting the latter operation, amputation of the cervix should always be done. In vaginal fixation he believed that labor should be induced. With ventral fixation, pregnancy to full term depended on the mobility of the uterus; if the cervix failed to enlarge and rose posteriorly, labor should be induced. The safest thing for these cases, however, was considered to be cæsarean section. In the reader's estimation the best method of suspending the uterus was by sutures introduced in front of the origin of the tubes instead of to the fundus. Two cases were reported, in one of which the

adherent uterus was the cause of pernicious vomiting, and mechanical intestinal obstruction. Labor was induced at seven months, and was accompanied by uterine inertia and post-partum hemorrhage. The cause of the adhesion had been parametritis following a previous abortion. In the other case there was an adherent uterus following ventrofixation, perineorrhaphy, and amputation of the cervix, thirteen months previously.

Dr. DUNNING of Indianapolis stated that he had done suspensory operations in 165 cases, eight of which became pregnant and terminated the same without complications. He suspended the uterus by three sutures, which formed one band between the organ and the anterior abdominal wall.

Dr. FRY of Washington had 150 cases, with fifteen cases of pregnancy, without complications and without any subsequent return of the prolapse. He thought the Alexander operation unsuitable, as it was apt to be followed by dragging on the round ligaments.

Membranous Endometritis.—Dr. F. F. LAWRENCE of Columbus referred to unsatisfactory results obtained from local treatment in this condition and proposed more radical measures. In forty-two cases seen he noted that tubal or ovarian disease were almost always present. In a considerable number the ovarian disease appeared to have followed the exanthemata. He believed that membranous endometritis was probably a secondary trophic disturbance due to the presence of an intercurrent pelvic disease, and suggested that when the condition of the tubes and ovaries was not due to infection, a cure of the endometritis might be secured by removing the diseased structures without in any way treating the uterus itself. He had successfully accomplished this result and recommended further and more extended trials. In all cases of membranous endometritis, which he considered a more appropriate term than membranous dysmenorrhœa, a careful examination should be made with these points in view.

Dr. FISCHER of Philadelphia thought the expulsion of shreds only not sufficient evidence to warrant the diagnosis of membranous endometritis, and said that among a large number of cases he had only observed two instances of this disease. He marvelled at the large number of cases observed by the writer.

Dr. Lawrence said that he did not propose this as an absolute recommendation, but offered it as a suggestion which had been borne out by facts. Many of his cases had expelled complete casts; but even the presence of shreds, he claimed, was sufficient to stamp the condition as a true membranous endometritis.

Management of the Acute Infective Stages of Abdominal Inflammation.—Dr. G. E. SHOEMAKER of Philadelphia read this paper, which might be summarized as follows: in some acute abdominal inflammatory types of disease, operate radically unless there is good reason for the contrary. As an example of this, he quoted appendicitis. In other types do not operate radically in the acute stage, unless there is good reason for the contrary, but operate in subacute or the chronic stage. Example of this was gonorrhœal salpingitis. Individual cases of all types of disease should be watched by a trained eye, as disaster was apt to follow any fixed rule. He concluded by noting the signs which point to operation and also measures useful in non-operative cases.

The officers of the section for the ensuing year, as selected by the Committee on Nominations, were as follows: *Chairman*, Dr. C. L. Bonifield of Cincinnati; *Vice-Chairman*, Dr. F. F. Lawrence of Columbus; *Secretary*, Dr. Manton; *Delegate*, Dr. J. W. Bovee of Washington.

SECTION IN SURGERY.

Third Day—Thursday, June 9.

The Anatomy of Inguinal Hernia; Andrew's Operation for Radical Cure.—Dr. D N. EISENDRATH of Chicago dealt with the general considerations on the anatomy of this subject, which he demonstrated by a very ingenious model explaining the objects to be accomplished by a radical cure. He gave his experience with the Andrew's operation and freely illustrated his paper by models and charts.

Three Years' Experience with the Autoplastic Suture for Hernia.—Dr. L. L. MCARTHUR of Chicago gave a final report of his experience with this suture, and stated that three years' experience with its use in inguinal herniæ encouraged the continuance of its employment. As a result of trying it in ninety-three cases and as judged by the histological findings in experimental work, he was justified in claiming that the transplanted tendon lived. He demonstrated this fact by an examination of the scar of a patient dead of a subsequent appendicitis a year after having an autoplastic suture.

Surgery of the Trifacial Nerve and Its Ganglia.—Dr. JOHN B. MURPHY of Chicago went very fully into this subject, which he divided into five stages: (1) Resections of branches down to the cranial foramina. (2) Division of branches within the cranium, with efforts to occlude the foramina. (3) Removal of the Gasserian ganglion, with intracranial segments of nerve. (4) Extraction of sensory root, and (5) intraneural injections, and made clinical reports with the result in eleven cases

Intracranial Neurectomy for Trigeminal Neuralgia, Cases and Comments.—Dr. HARRY M. SHERMAN of San Francisco gave a brief report of five operations on four patients, in three of which uneventful recoveries from the pain were secured. He mentioned some slight modifications in the incisions of the soft parts and of the bone, and recommended the pouring of salt solution into the skull before the suture to fill all vacant spaces and exclude the air.

Summary of the Final Results of Four Cases of Division of the Sensory Root for Tic Douloureux.—Dr. CHARLES H. FRAZIER of Philadelphia spoke of the theoretical advantages of this method over operative procedures and showed the immediate results obtained. He claimed to have had no evidence of recurrence, one, two, and three years after operation.

Dr. CHARLES K. MILLS of Philadelphia, Dr. WALTER G. SPILLER of Philadelphia, Dr. ROBERT F. WEIR of New York, Dr. J. SHELTON HORSLEY of Richmond, Va., Dr. CUSHING of Baltimore, and Dr. JOHN B. MURPHY of Chicago discussed these papers from various points of view, the general conclusions being that the relief of the condition was not as yet an assured fact by any of the methods mentioned, and Drs. Sherman, Murphy, and Frazier closed the discussion.

Laminectomy: A Further Contribution.—Dr. JOHN C. MUNRO of Boston reported from twenty-five to thirty cases of laminectomy and pleaded for the simplification in the technique as being important in reducing the severity of the operation.

Dr. LUND of Boston and Dr. CUSHING of Baltimore complimented the author on his excellent results and heartily endorsed the points he made.

Treatment of Cold Abscesses and Sinuses in Tuberculous Disease of Bone.—Dr. V. P. Gibney of New York took up the routine surgical treatment of the day and dwelt extensively on the orthopedic treatment, bacteriologic findings, value of asepsis from beginning to end, and comparative results of the methods employed.

Old Unreduced Dislocations.—Dr. DE FOREST WILLARD stated: (1) Early immediate diagnosis was the most important element in the prevention and treatment of all dislocations. With ether, the *x*-ray and anatomical and surgical knowledge, the displacement should always have been discovered by the surgeon. His only excuse for non-recognition would have been extreme injury in other portions of the body. (2) An unrecognized or unreduced dislocation should have been carefully examined under ether to discover the extent of adhesions and the possibility of affecting reduction without measures; failing in this,

continuous extension in bed should be practised for several weeks; the second attempt, without the application of extreme force, should be made, the permission of the patient having been previously obtained to permit of open operation if deemed necessary. (3) Open section should include the division of all muscular, tendinous, capsular, and bony obstacles to reduction. When the socket is filled up with dense fibrous tissue, such tissue should be excavated and the head of the bone displaced *in situ*. (4) Partial or complete excision of the head and of fragments in case of fracture, was frequently necessary. (5) In cases that had existed more than a year, or in which the original injury had been extreme, operation should be avoided unless pressure upon nerves or blood-vessels was seriously impairing the usefulness of the limb or giving pain. Resection should be reserved for bad late cases with pain and serious nerve symptoms. Sepsis was frequent on account of the severity and length of the operation. (6) Pain and disability were the two most important measures in arriving at a decision concerning operation. When a limb was useful in its new position, gave no pain or difficulty, it should be left alone. (7) In the after-treatment, muscular gymnastics, electricity, and massage were very important measures and should be persistently employed.

Conservative Perineal Prostatectomy: Report of Fifty Cases.—Dr. Hugh H. Young of Baltimore called especial attention to the absence of mortality and the simplicity of the procedure, many of the patients being over seventy-five and some over eighty years of age, and laid stress on the importance of cystoscopy and careful preliminary treatment.

Prostatic Obstruction.—Dr. Parker Syms of New York read a fully illustrated paper on this subject.

Prostatectomy in General, Especially by the Perineal Route.—Dr. George Goodfellow of San Francisco gave the indications for his adherence to the perineal route, described his method of operating, referred to the mortality in seventy-five cases operated upon by this method, and gave the ultimate results of each.

Is It Wise to Try to Make Any One Operative Method Apply to All Prostatectomies?—Dr. Eugene Fuller of New York read a paper so entitled, which he opened by stating that the results obtained by prostatectomy had put the operation on a firm footing. Numerous surgical makeshifts were brought forward, when the operation was first introduced, to compete with the radical operation. Most of these had now been discarded, owing to the unsatisfactory results attending them and to the increasingly better results following prostatectomy at skilled hands. The criticism was made that most of the present writers on the subject concerned themselves only with the problem of operative removal of the prostate, the questions of after treatment and general management receiving little or no attention. All prostatectomies were grouped under three headings: (1) Where the hypertrophy is removed through the employment of a suprapubic cystotomy; (2) where it is removed through the employment of a perineal cystotomy; and (3) where it is extracted along the path of a perineal dissection, the aim of which is to avoid opening the urinary tract or the rectum. As far as the mere removal was concerned, he stated that it could be done by any one of the three methods, and then discussed the pros and cons of the different methods, but few cases were found in which the third method seemed advisable. When performed according to Dr. Fuller's ideas the second method was advocated for most cases in connection with which there existed good expulsive force to the bladder. Where this was impaired and where serious lesions of the urinary tract existed the suprapubic operation was the one usually chosen. He called attention to the fact that most writers showed a strong tendency to try to make some special form of the perineal operation apply to all cases and to entirely discard the suprapubic operation on the ground that it was either unnecessary or operatively extrahazardous. These objections were ably met. The suprapubic operation, it was asserted, should in itself give no extra mortality if certain rules were observed in its performance, if the incision was properly sutured and drained, and if the surgical supervision of the after-treatment was efficient. The value of the suprapubic vesical drainage vent, a feature connected with the suprapubic operation, was especially dwelt upon. The establishment of such a vent, Dr. Fuller stated, decided him to choose the suprapubic operation in a certain class of cases. In conclusion, a protest was entered against classing as true prostatectomy cases of middle-aged or even younger men which represented simple inflammatory effusions in connection with the prostate or its periphery. In such cases an operator attempting prostatectomy would find nothing to enucleate, or for that matter to remove.

Dr. Orville Horwitz of Philadelphia, Dr. Robert H. M. Dawbarn of New York, Dr. John C. Munro of Boston, Dr. Martin B. Tinker of Cornell, Dr. D. N. Eisendrath of Chicago, and Dr. Archibald McLaren of St. Paul freely discussed these papers and endorsed most of what had been said, the authors closing.

Kidney Stone; Diagnosis and Treatment.—Dr. Arthur D. Bevan of Chicago took up the question of etiology, symptoms, differential diagnosis, prognosis, technique of operative procedures, and the question of recurrence after operation.

Fourth Day—Friday, June 10.

The Treatment of Fractures of the Patella by Lateral Sutures.—Dr. Jos. A. Blake of New York dwelt fully on the anatomy of this subject and reported the results of eighteen operations both as to union and as to function according to his method.

Surgical Treatment of Certain Cases of Arthritis Deformans.—Dr. Martin B. Tinker of Ithaca, N. Y., presented this paper and stated before beginning a discussion on this subject that it was necessary to keep in mind the exact character of the disease under consideration. He said the condition was not a subacute or chronic rheumatism or tuberculosis, but a distinct diseased condition characterized by its long course, with progressive involvement of many joints, which lead eventually to absolute disability from ankylosis. Many interesting suggestions, he stated, had been made as to the etiology of the affection. In some cases it followed severe nerve-strain, and the nervous element was no doubt an important factor. Disturbance of metabolism, he stated, was also always present, but these were probably only contributing factors. The infectious origin seemed most probable, as several cases had been observed in which the disease had developed directly after a severe infection. He stated pain, swelling, and stiffness of the joints were the most important symptoms; the pain gradually ceased as the joints became fixed. The swelling at first was from effusion, but this would soon disappear, and later the enlargement was from bony or fibrous thickening. He stated that the use of tuberculin was of great value in the diagnosis in distinguishing it from tuberculosis, a condition with which it might be confused. He stated that in the treatment both palliative and operative measures should be considered; as a rule, the general principle followed in the treatment of joint trouble, to put the joint at rest, was reversed, for if the joint was kept quiet, stiffening was certain to occur at once. Gymnastics, massage, and passive motion were to be judiciously employed; baking at from 280° to 350° Fahrenheit was of value, as were also the use of various forms of baths; general hygienic measures were also of importance. In the operative treatment forced motion under anæsthesia was condemned, for the stiffness was not from adhesions, but from bony deposits and change of the contour of the bones affected. Arthrotomy and excision of osteophytic deposits might be employed where the stiffness of the

joint was dependent upon the pressure of only one or two such bony prominences that lock the joint and where the acute symptoms had entirely subsided. Excision of the joint was indicated in cases of complete ankylosis, to restore motion, and often enabled the patient to feed and dress himself and perform other necessary duties impossible with an ankylosed joint. He stated that operative treatment was limited to a comparatively few cases of this kind. The condition was generally a most pitiable one and the general condition was incurable.

Impacted Fractures of the Neck of the Femur.—Dr. Le Moyne Wills of Los Angeles reported two interesting cases, which he illustrated with radiographs. He laid particular attention on the marked difference in treatment in each case and to the good results obtained.

Fat Embolism of Lung, Following Fracture, with Report of Two Cases.—F. Gregory Connell, M.D., of Leadville, Col., reported two cases of fat embolism of the lung which followed fractures of the long bones, both of which recovered. In a study of the history of the subject he found that about 250 cases had been reported, and of these not over a dozen had been contributed by American writers. The anatomy of the parts involved was reviewed, and among the causes other than fracture are enumerated orthopedic operations, open operations upon bones and joints, surgical operations on structures other than bone, inflammation of bone or periosteum, laceration, bruising or suppuration of the fat containing soft parts, or extensive burns or scaldings, rupture of fatty liver, and also causes that had arisen within the circulation, such as atheromatous changes of the vascular wall, fatty changes of the thrombi of various origin and location, diabetes, icterus, etc. The symptomatology was considered at length; the milder form was rarely diagnosed, and was of little import; the acute and rapidly fatal form was rarely differentiated from shock, and was often unsuspected. The ordinary form of fat embolism, that was recognized as such, usually presented the following symptoms: An interval of euphoria; lipuria or fat in the sputum; extreme debility, anxiety, malaise, somnolence, pallor, cyanosis; respiration, rapid and irregular, with dyspnœa, cough, pain, hæmoptysis, râles, œdema, or consolidation; pulse, feeble, irregular, and rapid; temperature unreliable; loss or diminution of sensibility, and of the reflexes, pupils contracted, Cheyne-Stokes respiration, spasm, convulsion, vomiting, paralysis of coma. Each of these are considered pro and con, but the temperature, which was perhaps the most perplexing and unsettled symptom of fat embolism, was gone into at length, and it was concluded that the temperature might be high—in thirty-seven cases in which the temperature was given, that were collected from the literature, twenty-nine had an elevation of the temperature, while in the eight the temperature was mentioned as being either normal or subnormal. The diagnosis during life was first made by Lucke, and in the same year, 1873, by Bergman; the first in America to diagnose the condition during life, was the late Christian Fenger, in 1879. Among the conditions more likely to be confused with fat embolism might be mentioned: Shock, septicæmia, pulmonary embolism, and less commonly, the effects of anæsthetics, congestion of the lungs or kidneys, cerebral hemorrhage, concussion of the brain, atheroma of the coronary arteries. The prognosis was most uncertain, owing to the fact that the frequency of the condition was unknown. Fat embolism of a greater or lesser degree followed practically all fractures, but it gave rise to serious symptoms comparatively seldom. The fat in the circulation had no deleterious effect upon the blood; its sole action was a mechanical one, in obstructing the capillaries. The treatment was unsatisfactory—in fact, it might be said that there was no treatment. Prophylaxis would consist of gentle handling of the limb, so as to rupture as few fat cells as possible, and then immobilization. After the symptoms were present, drainage, as it lessens the tension at the site of the injury, might be of advantage. But the closest attention should have been given to the heart, and as the bulk of the fat was eliminated through the kidneys, attention should also have been given to these same organs.

Cincinnati Academy of Medicine.

At a regular meeting of the Academy, held on April 18, Dr. B. Merrill Ricketts presented four cases. A case of excision of the elbow-joint for ankylosis with an excellent result and three cases of hernia, one a double inguinal hernia with perfect result and two cases in which three operations had been necessary before a good result was secured. Dr. Ricketts laid the failure of the first two operations in each case to the use of faulty sutures. Dr. Edwin Ricketts showed a tube and ovary removed from a woman in the child-bearing period. She had had several attacks of severe pain with some bloody discharge from the uterus. On removal, the tube was found distended with blood and was believed to be an extrauterine pregnancy. Microscopical examination had not yet been made.

The paper of the evening was read by Dr. John E. Greiwe entitled, "Aortic Lesions." He said in brief:

Our greatest advance in the comprehension of aortic lesions has come from the study of their etiology, and we will do most good by using this knowledge in their prophylaxis and treatment. Lesions of the aortic orifice are always of grave importance and are always very difficult to manage. The increase of blood pressure in the left ventricle with the necessary increase of labor involved the tendency to degeneration of the muscular wall, the greater danger of cerebral involvement and the frequent involvement of the mouths of the coronary arteries are some of the special dangers of these lesions. In these cases we must study not the heart alone but the condition of the whole circulatory system and the remote organs. Of 854 autopsies at the Cincinnati Hospital, 160 showed well-marked heart lesions, 43 involved the mitral valves alone, 42 the aortic valves alone. In 38 both mitral and aortic valves were diseased. In two cases the tricuspid valves were diseased in combination with disease of the mitral and aortic valves. Sixteen cases showed pericarditis, 10 with adhesions; of these 10, five were associated with aortic disease and two with mitral. The remaining 19 cases showed muscular change or disease of the coronary arteries. These figures show the relative frequency of aortic and of combined lesions.

Known causes of aortic lesions are acute infections, especially acute rheumatism and scarlet fever, alcoholism, syphilis, gout, hard manual labor, sudden severe strain, lead poisoning, nephritis, excessive use of coffee and tobacco, chronic intestinal autointoxication, and last but not least, conditions that give rise to long continued and oft repeated high tension in the circulatory apparatus. Chronic poisoning from whatever cause destroys the elasticity of the blood-vessels, hard labor and long continued stimulation by coffee, tea, and tobacco cause high tension and later impair the elastic coats of the vessels. Sudden strain may cause rupture of valves with regurgitation and sudden collapse. Of all causes or associated conditions, nephritis is most important, and of 160 cases, 89 showed marked kidney change, mostly interstitial, but parenchymatous changes and pyelonephritis were not uncommon. The importance of uranalysis in these cases and the good effects of diet and eliminative treatment are well known.

In regard to long continued and oft repeated high tension, there can be little doubt that the heart responds to all the emotions of the central nervous system, and the writer believes that profound emotions, such as are almost constantly present in cases of hysteria, neurasthenia, melancholia, etc., are frequently, by raising the blood pressure, responsible for disturbances which at first may be purely functional, but later may produce organic changes in the blood-vessels and secondarily in the heart itself.

The real etiology and pathology of these cases is still uncertain, but it is certain that long continued high tension leads to a loss of elasticity in the middle coat of the arteries with changes in the intima and tremendous backdamming on the aortic valves. No fruits may be present for a long time, but the second aortic tone is much accentuated and tachycardia is frequent.

The writer has taken sphygmographic tracings and measurements of blood pressure in a number of these cases. Miss C., thirty-four years, suffering from neurasthenia, has very high blood pressure with the Riva Rocci instrument, 228; Gaertner, 200; and Basch 215. Pulse 88, second aortic tone much accentuated. Elastic waves are poorly marked in the tracing, showing loss of elasticity. Miss S., age thirty, also suffering from neurasthenia with high tension. Pulse 116, Riva Rocci 133, Basch 120, and Gaertner 110. In this case the first aortic tone was roughened and the second accentuated, the elastic waves of the tracing were diminished. The patient is subject to attacks of tachycardia with semi-consciousness and lividity. Both tracings show the "pulsus tardus" of high pressure. Other sphygmograms from aortic lesions were shown, showing well-marked "pulsus tardus," and in one instance "pulsus rotundo tardus" due to high tension and loss of elasticity in the blood-vessels. In one tracing a well-marked "water-hammer pulse" was shown.

As regards treatment, prevent the trouble as far as possible by treating the predisposing conditions. When the trouble has begun prevent further damage by attention to diet, hygiene, medication, and regulation of the work to be done. Avoid strain, physical and mental. As said above, high pressure is often responsible and should be relieved by attention to the kidneys, and often the intestinal tract will be found to be the exciting cause.

Venus stasis should be relieved by mild exercise or passive movements, and systematic breathing exercises should be carried out. The Nauheim treatment relieves high tension by bringing about a freer flow through the capillaries, and can be carried out at home by the use of a powder prepared for the author in this city.

Following the paper, Dr. Greiwe demonstrated a number of pathological specimens from the Cincinnati Hospital Museum and several instruments for measuring blood pressure.

Books Received.

While the MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

ILLUMINATING GAS POISONING: A CLINICAL STUDY OF NINETY CASES.*

BY W. GILMAN THOMPSON, M.D.,
NEW YORK.
PROFESSOR OF MEDICINE IN THE CORNELL UNIVERSITY MEDICAL COLLEGE IN NEW YORK CITY.

IN view of the frequency and seriousness of poisoning by illuminating gas, it is a surprise that the condition has not received more attention in medical literature, for it presents a number of interesting phenomena, such as an eccentric fever, a high degree of leucocytosis, and a large group of nerve symptoms, besides various practical problems. It has been my experience to meet with three fatal cases and a number of others in private practice besides many in hospital service. The conclusions herewith presented are based upon a study of ninety cases, a large proportion of which were treated at the Presbyterian Hospital in the service of my colleagues or myself. This series of ninety cases includes twelve in which autopsies were performed. None but comatose cases have been included, and of the ninety cases only seventeen, or 18.8 per cent., were fatal.

The lack of systematic nomenclature and coöperation in methods of securing the data of Health Board statistics in the large cities of this country is strikingly illustrated in an attempt to secure such data for this article, thus the condition under discussion is variously classed under such titles as "coal gas poisoning," "asphyxia," "illuminating gas poisoning," "poisoning by noxious gases," etc. For example, in the Philadelphia Health Board Annual Report for 1900, I was surprised to find only one case under the heading "poisoning by illuminating gas," until I unexpectedly discovered in the same document five more cases under the somewhat indefinite heading "suffocation by gas." There were doubtless other cases similarly diagnosed. In Boston there have been as many as forty-three fatal cases in a year. In the Baltimore Health Board report for 1900, eleven cases are recorded under the title "asphyxia" from gas inhalation and sixteen more under "noxious gases," presumably illuminating gas in most instances. In Chicago, in 1898, the Health Board reported forty-five deaths from asphyxia by gas, and there were a few more probable cases under dubious headings. This inaccuracy of reports makes impossible any attempt to secure accurate data upon a large scale. In New York City, in 1901, the Health Board reported ninety-nine suicidal (forty-two females, fifty-seven males), and 189 fatal, non-suicidal cases of illuminating gas poisoning, making the important total of 288. In Bellevue Hospital alone, during the first three months of 1904, thirty-two cases were treated, with six deaths. If the mortality ratio represents a fair average, there must be little short of 2,000 cases in all occurring each year in New York City, a number which emphasizes the importance of more thorough study of the condition than it often receives. This great preponderance of cases in New York City is readily explained by the prevalence of cheap gas fixtures and gas stoves in the tenements, and by the large annual arrival of ignorant pauper foreigners who have never used gas or who, through poverty and nostalgia, become despondent and suicidal.

In 1900 W. Sachs,[1] in an important monograph, collected from the entire literature references to 420 articles published up to that date upon illuminating gas poisoning, to which Alexander Panski[2] added six more, bringing the list up to March 16, 1902. Many of these articles, however, are reports either of isolated cases or of purely experimental research. A few small series of cases have been published, but, in so far as I am aware, the present series is the most extensive from which an attempt has been made to draw comparative clinical deductions.

The chief difficulty in the study of this type of poisoning lies in the impossibility of estimating the quantity of gas inhaled and the degree of its dilution, as well as the duration of the inhalation.

The majority of hospital cases are brought to the hospital during the early morning hours. An ignorant, careless, or drunken person goes to bed at night in a room in which there is a gas stove or gas jet with a loose cock or leaky pipe, the danger of which is unrecognized. Falling into a sleep, made heavy by fatigue or drunkenness, the patient, without awakening, becomes gradually asphyxiated, at first with a well-diluted mixture of gas and air, and later by almost undiluted gas. As coma deepens, the loud sterterous breathing of the patient, or the odor of gas escaping beyond the room, attracts the attention of some early riser, who gives the alarm and sends the patient to the hospital. Hence it happens that a majority of the hospital patients are those who have been inhaling gas for six or eight hours in increasing strength, and who have probably already been in coma for at least four or five hours.

In several instances the careless flinging of a towel or coat over the gas-bracket just before the patient got into bed, caused a reopening of a gas-cock which had been turned off. Some of the most serious cases arose in connection with the use of gas stoves, the pipes of which usually discharge much more gas than those of single illuminating burners. There are a few other cases in the series among workmen who have been suddenly asphyxiated by almost undiluted gas, or among those who, with suicidal intent have deeply inhaled the gas from a tube and have thus been suddenly overcome by it.

Although, as stated, it is difficult to estimate the volume of gas inhaled in the series of cases reported, enough had been taken in almost every instance to render the patient comatose for at least an hour, if not much longer, after discovery. The minor effects of chronic gas poisoning in slight degree, such as anæmia, vertigo, various forms of indigestion, muscular weakness, etc., will not be dealt with in this discussion.

Among the ninety cases of the series, twelve pa-

*A paper read at the meeting of the Association of American Physicians, May 10, 1904.

tients were definitely known to have attempted suicide, and there were probably as many more who, upon recovery, were unwilling to acknowledge it. This is rendered the more probable from the preponderance of young women among the patients. The patients comprise fifty-three females and thirty-seven males, and their ages ranged from four months to seventy years.

In most of the cases of this series ordinary illuminating gas was inhaled, containing certain volatile hydrocarbons, besides from 5 to 10 per cent. of carbon monoxid, but in some cases water-gas was inhaled, containing from 20 to 30 per cent. of CO. It has been shown experimentally that one-tenth of one per cent. of CO, when inhaled, causes discomfort, restlessness and dyspnœa, and between 1 and 2 per cent. may be fatal. It is well known that the gas forms a relatively stable compound with the hæmoglobin of the blood, thus markedly interfering with the oxygen-carrying power of the red corpuscles, but it also possesses a second, more important, direct toxic effect upon the central nervous system of the nature of a narcotic and depressant.

That it causes a displacement of the nascent oxygen of the red cells, and thereby deprives the tissues and nerve centers of the body of oxygen, is not a sufficient explanation of the clinical phenomena of illuminating gas poisoning. These phenomena, especially those emanating from the nervous system, are too complex to be accounted for otherwise than through some specific toxic influence of the gas itself upon the central nervous system. Moreover, these symptoms appear in cases in which there is still a large percentage of red cells unaffected by CO, and they often persist long after all CO has left the blood. For example, in Case 43, the red cells on the sixth day numbered 5,440,000 and the hæmoglobin was 95 per cent., yet the patient died two days later with apparently normal lungs, as well as normal blood.

In Case 46, on the eighth day, the red cells numbered 5,400,000 and the hæmoglobin was 95 per cent. On the twenty-first day the red cells were 4,944,000 and the hæmoglobin was 100 per cent., but the fever, leucocytosis (18,200), and a feeble state still existed. That the hæmoglobin at this date was normal was proved by spectroscopic examination.

The *leucocytosis* is a very important symptom. Most of the cases came under observation before the value of differential counts was appreciated, and some of them before even a general leucocyte count was in vogue, hence I am unable to offer differential counts. A general count was made in twenty-nine cases, in all but two of which a considerable increase above the normal was observed. In eighteen of the twenty-nine cases a leucocytosis above 18,000 was determined. Among adults the highest non-fatal cases registered respectively 44,000, 32,000, and 31,000. In the mild case of an infant of four months, the count was 52,000, but it is naturally high in infancy.

It is an interesting fact that in every fatal case in which a leucocyte count was made, it exceeded 18,000, the two highest counts being each 50,000.

The maximum leucocytosis is usually attained within the first twenty-four hours, but sometimes not for forty-eight hours. Afterward it subsides slowly, and in the more severe cases it persists more than a week and outlasts the coma and many other symptoms. A leucocyte count above 18,000 or 20,000 is always a symptom of grave import, although it does not make the prognosis necessarily fatal, and even in fatal cases there may be a gradual subsidence of the number of white cells, as illustrated by Case 58, in which the leucocytes on succeeding days were counted as follows, commencing with the first: (1) 50,000, (2) 38,500, (3) 14,300, (4) 14,200, (5) 13,800, (6) 13,800. This patient died on the sixth day from bronchopneumonia. The following cases are cited in support of the above statements:

Case 33.—Admission count, 22,000. Six days later leucocytosis (11,300), yet the coma lasted only eight hours and the temperature did not rise above 101.5.

Case 46.—Leucocytosis lasted twenty-one days, during which time the patient remained either comatose or delirious, and the maximum temperature was 103° F. The maximum leucocyte count was 21,800 and the minimum 13,800. The red cells and hæmoglobin percentage, first estimated on the sixth day, remained normal.

Case 45.—The admission count was 14,600. The following day it fell to 7,700, and the patient recovered.

Case 4.—The admission count was 44,000; two days later it fell to 15,000; coma lasted only one day, and the temperature did not exceed 101.5. On the sixth day the patient recovered.

Case 62.—This patient was comatose for only three hours after the time of first exposure to the gas, yet the leucocyte count was 14,000. A differential count showed: polymorphonuclear cells 92.3 per cent., lymphocytes 3.3 per cent., large mononuclear cells 4.1 per cent., eosinophiles 0.3 per cent.

Case 31.—The admission count was 13,500; the following day it rose to 21,200, and the patient died in coma on the fourth day.

In explaining the leucocytosis, no doubt some allowance should be made for the stasis in the peripheral vessels accompanying cyanosis, but that this is not the sole cause is demonstrated by the fact that leucocytosis is observed in mild cases with vigorous pulse and no cyanosis, and in other cases it persists after cyanosis has disappeared. It certainly does not accompany, as in hemorrhage, a numerical loss of the red cells, for they remain normal in number, and, moreover, it often exceeds in degree the leucocytosis of that condition. It would appear to be a justifiable conclusion that it is due to some specific action of the gas, such as may occur in ptomain poisoning. (In a case of the latter toxæmia I have records of a leucocytosis exceeding 15,000.)

I am indebted to Dr. Herbert S. Carter for an analysis of the chlorides and urea of the blood in five non-fatal cases. According to Halliburton[3] the average percentage of chlorides in normal blood is: sodium chloride 0.27, potassium chloride 0.205: total chlorides 0.475. In Carter's cases the total percentage was as follows: (1) 2.5, (2) 1.4, (3) 1.01, (4) 0.62, (5) 0.57, showing a considerable increase in several instances.

According to Halliburton, the urea percentage of normal blood lies between 0.02 and 0.04, whereas in four of Carter's cases the analyses gave (1) 0.063, (2) 0.057, (3) 0.05 and 0.037 respectively.

The *temperature* of the body is elevated in almost all the unconscious cases, and fever lasts from one day to a week or more, the average duration being about three days. The temperature does not afford a definite index of the severity of the case, for there may be a low temperature with coma, as in Case 6, in which the temperature did not rise above 100° F., although the patient remained unconscious four hours after being brought to the hospital, or there may be a high temperature with normal consciousness.

In eight cases there was a preliminary fall before

the rise of temperature, as shown in the following group:

Case 6.—The admission temperature was 97° F., but the pulse was 120 and respiration 28. Subsequently the temperature rose to 100°F., with the same rate of pulse and respiration.

Case 8, in which the patient's admission record was temperature, 96.4°F.; pulse, 126; respiration, 30. In this case the maximum temperature, 101.5°F., was attained on the second day, but the pulse rate fell to 84, and the respiration to 20. Unconsciousness lasted one hour after admission.

In Case 9, although deep coma lasted for ten hours, the admission record was, temperature, 99°F.; pulse, 150; respiration, 30, and the maximum temperature, attained on the evening of the first day, was 100.2°F.

Case 18.—The admission temperature was 96.5° F., pulse, 92; respiration, 26. Within six hours the temperature rose to 101.5° F.; pulse, 140; respiration, 40; and the next morning the temperature became subnormal.

Case 25 was that of an infant of four months. The child's nurse was playing with it when she discovered a strong odor of gas and fell unconscious; she soon recovered, but the infant continued unconscious for about half a day. The temperature remained at 98° F., but the leucocyte count was 52,000, somewhat above the normal for an infant. Recovery was prompt.

In Case 50 the admission temperature was 96.5°, and within twenty-four hours it rose to 102.8° F. After convalescence from the gas poisoning, neuritis and erysipelas developed.

Case 58.—The admission temperature was 95° F.; pulse, 98; respiration, 28. During the day, and following phlebotomy and infusion, the temperature rose rapidly to 102° F. with the same rate of pulse and respiration. The temperature continued to rise for five days when just before death it reached 107° F. The patient had been exposed all night to the gas, and remained comatose throughout.

Case 60.—The admission temperature was only 96° F., although the respirations were 40 and the patient remained five hours in coma before death. Possibly subnormal initial temperature would be more often found except for the fact that most patients have been unconscious for several hours before discovery. The character of the temperature varies so much that it is difficult to construct a typical curve. Thus the maximum, usually attained on the first day, may be postponed for one or two days, and a day of normal temperature may intervene between two febrile days. Usually the temperature is remittent and the subsidence is by lysis, and in about one-third of the cases, during convalescence, it becomes subnormal, often falling as low as 97° or 96° F. In Case 15 the temperature, after reaching 96° F., remained for five days at 97° F.

Case 56.—Illustrates two causes of modification in temperature which may affect the ordinary toxic fever of gas-poisoning, namely infusion and pneumonia. The patient was admitted with a temperature of 101.8 F., pulse 120, respiration 48. After a phlebotomy of 8 ozs., and infusion of 1,000 c.c., the temperature rose to 105.5 F., without alteration in the rate of pulse or respiration. A chill accompanied this elevation of temperature. The latter fell very rapidly 6.5° F., so that the next morning the record was 99° F. with pulse and respiration unchanged. The second day the temperature rose again to 105° F. and the patient died on the fifth day of pneumonia.

Case 19.—This patient, an ignorant foreigner, blew out the gas on retiring, being unfamiliar with its effects. He had one of the most protracted fevers of any of the uncomplicated cases recorded in this series: for nine days the temperature ranged between 100° and 102° F., for four days more it reached 100°, and then for two days remained subnormal, falling to 97° F. On the first day, a temperature of 102° F., which would have been apparently the limit of toxæmia temperature, was interrupted by the chill and elevation of temperature to 108° F., following phlebotomy (8 ozs.) and infusion (1,000 c.c.). The corresponding pulse was 160, and respiration 56, and leucocytosis 24,300. Recovery.

The vagaries of temperature are, I think, explainable on the ground of disturbance in the normal chemical processes of the body, and circulatory unbalance consequent upon the altered pulse and respiration, rather than by the assumption of any specific thermogenetic action of the gas. Other gases and vapors inhaled, like the anæsthetics, do not produce fever, nor do chemical poisons as a general rule, unless they give rise to inflammation, although there are some exceptions to the latter statement, as, for example, the case of a child of two years who was admitted to the hospital within half an hour after accidentally drinking kerosene. The admission record in this case was: temperature 102.5° F., pulse 160, respiration 60. The following day the temperature was 103° F. and the patient was drowsy and feeble, but finally recovered.

The maximum temperature recorded in any of this series (excepting Case 19) was 107° F., and this case terminated fatally. The maximum record in any non-fatal case (excepting Case 19) was 104.8° F. (Case 42). The maximum duration of elevated temperature in any non-complicated case was twenty-two days.

An interesting case with hyperpyrexia is reported by William A. Steel of Philadelphia (*Philadelphia Medical Journal*, February 16, 1901). The patient was a girl eight years of age. The temperature rose rapidly after coma began, and within eight hours reached 110° F. with heart-beats of 215, the pulse being imperceptible. After the use of oxygen, hypodermoclysis, a cold plunge and vigorous hypodermic stimulation, the child recovered and was discharged cured from the hospital on the fifth day.

The *pulse* is markedly accelerated, and usually out of all proportion to the temperature and respiration. It is seldom below 120 nd frequently reaches 136 or 140 during the coma. For example, in Case 24 the pulse rate was 150 while the respiration rate was 30 and the temperature only 100.2° F. during coma. The pulse is usually, but not invariably, much weakened, but remains regular in rhythm. In other words, the pulse conveys the impression that the heart is being irritated directly or through its nerves by some specific form of poison. The acceleration is certainly not secondary to any changes in the lungs, for it is observed in many cases in which the physical examination of the lungs is entirely negative, as in Case 11, with a pulse of 142, nor is it due exclusively to the deprivation of the blood of oxygen, as it exceeds in degree what would be expected under those circumstances.

The maximum pulse rate observed in any of the non-fatal cases among adults was 150.

The *respiration* is accelerated irrespective of the condition of the lungs. It averages about 30 but I have records of 12 cases in which it reached 36 or more, although physical examination of the lungs was entirely negative. It is apt to be labored or jerky in type, and with profound coma it may be-

come of Cheyne-Stokes irregularity. This type of dyspnœa occurring independently of pulmonary œdema or congestion is necessarily of central origin, due either to the lack of oxygen at the medullary center or probably to the direct toxic irritation there of CO or some other ingredient of the illuminating gas.

The maximum rate of respiration observed in any non-fatal case of the series was 62, although it reached 80 in a fatal case.

In not a few cases artificial respiration was maintained for a long time with the effect of prolonging life to recovery. In the two following cases the respiration rate was extremely slow for some time after admission:

Case 27.—The patient, designing suicide, took the tube of a gas stove in her mouth and inhaled the gas for ten minutes. She was found pulseless, with respirations of only five per minute. Artificial respiration was performed, and hypodermic stimulation was given; she became conscious in fifteen minutes and recovered without fever, although the pulse reached 120.

In Case 42 the respiration on admission was only two or three per minute, and artificial respiration was maintained for an hour. Phlebotomy and infusion were performed and the breathing improved, the rate rising to 32. (Recovery.)

Digestive disturbances are observed but are not severe or characteristic. Constipation is the rule, and vomiting sometimes occurs, more often in the mild cases or during convalescence from coma; it became severe in eight cases of the series.

Extreme dryness of the mouth, and congestion, redness, and dryness of the pharynx were observed in many cases.

Several patients experienced excessive *perspiration.*

The *urine* presents no special peculiarities. It is often of high specific gravity, 1,025-1,032, and the proteid waste is usually somewhat increased. A heavy deposit of uric acid is common. Albuminuria was noted in twenty-six cases of the series. In many the albumin was represented by a mere trace, in others there was 10 per cent. by volume, with hyaline and granular casts. As many of these cases occurred among the alcoholic or those of advanced years, it is probable that the gas has no direct influence in producing albuminuria, although it was observed in an infant of four months.

Case 55.—In this fatal case, methæmoglobin was found in the urine on the first day and again on the third. In several other cases in which it was searched for, it was not present.

In many cases there was retention of urine and catheterization was often necessary, even after consciousness was regained. In the majority of cases constipation was obstinate, and repeated doses of cathartics and enemata were required. In eight cases there was incontinence of both urine and fæces, in some instances persisting three or four days, and outlasting the stage of coma by two or three days. In a few more cases there was incontinence of urine alone.

The *pupils* present such varied appearances that there is nothing typical about them. In fully one-fourth of the cases they appeared normal and reacted normally. In twelve cases they were distinctly enlarged, sometimes with, sometimes without reaction to light. In a half dozen cases they were diminished, twice they were unequal in size, and in two cases there was temporary nystagmus, one presenting also lateral deviation of the eyeballs.

In one or two cases a sensation of fulness and ringing in the ears was complained of, and in one instance deafness persisted for a day in one ear.

As stated above, the *nerve symptoms* are so varied as to force the conclusion that illuminating gas acts as a direct poison to the central nervous system, for they cannot all be accounted for upon the theory that the gas acts alone by depriving the red blood corpuscles of their ability to transport oxygen. These symptoms are: tremors, muscular twitching, convulsions, rigidity, opisthotonos, anæsthesia, increased reflexes, headache, and coma.

The nerve symptoms vary with the mode of poisoning. When the patient is awake, and inhales the gas slowly or well diluted, he experiences headache and vertigo, often accompanied by nausea and vomiting with muscular prostration. Evidence of vasomotor paralysis appears in burning sensation in the skin, especially of the face, and in redness of the cutaneous surface. Later the lips and extremities become bluish, although, owing to the peculiar cherry-red color imparted to the blood by CO, the ordinary duskiness of extreme cyanosis for some time may remain absent. It is important to note that the degree of cyanosis is independent of any changes in the lungs, such as congestion, œdema, etc., and is often extreme, while the lungs remain normal.

The patient meanwhile experiences visual disturbances, confusion of ideas, and becomes drowsy, perhaps delirious, anæsthetic, and finally comatose.

In cases in which the patient is poisoned while asleep or under the influence of alcohol, or in cases in which a large quantity of the concentrated gas is at once inhaled, the preliminary nervous phenomena above mentioned are absent, and the patient passes at once into coma without wakening. The coma, which is always profound, is usually accompanied by loud stertorous breathing, and sometimes by dilated pupils, and involuntary evacuation of fæces and urine. In some cases, after hours of unconsciousness, the patient may be partially aroused to take nourishment only to relapse again. The coma may last from half an hour to many days, and it is usually accompanied, as stated above, by elevation of body temperature and a rapid feeble pulse, but there are afebrile cases of coma, as there are cases in which it is the chief and almost the only symptom. In Hewetson's case the coma lasted nine days and was fatal. In Case 46 it lasted ten days.

As the patient slowly regains consciousness, he may suffer for days from mental weakness, dulness, and confusion with loss of memory. Paresis or spasm of the extremities may persist for several days after coma with muscular weakness, but in the majority of cases complete recovery is fairly prompt without sequelæ.

A large number of cases have been reported in recent years in which there were interesting symptoms referable to the brain, cord and peripheral nerves, symptoms which can be well explained after a review of the reported autopsies which follow (p. 45):

Bruneau[5] reported a case of hemepligia following gas poisoning. Frinkelstein,[6] one of dementia, and A. Scott,[7] one of acute mania with recovery, after ten days. Zeiler[8] reported a case of leptomeningitis serosa. Bruns[9] reported a case of disseminated encephalomyelitis, and Alexander Panski,[10] another in which the patient was ill for months with paralysis of the legs and arms, sensory and speech disturbances, anæmia and mental weakness. Becker[11] reported a case with multiple sclerosis. Cases with multiple neuritis have been reported by Glynn,[12] Meczkowski[13] (three cases), Skowrouski,[14] Brugman and Gruzewski[15] (six cases), and others.

The only occasional sequelæ apart from those above described referable to the nervous system, are bronchitis, bronchopneumonia, and lobar pneumonia. Small mentions diabetes as a possible sequel; it was not noted in any of the cases of my series. Pleurisy was observed once. Tuberculous patients did not appear to suffer more than those with normal lungs.

The assertion is made by Small (XX Century Practice of Medicine, Vol. III, p.589) that the chance of recovery lessens with the duration of exposure to the gas, and that after eight hours of coma there is very little chance of recovery, yet this is by no means an infallible rule—for example, Hewetson reported, in the Johns Hopkins Hospital Bulletin for 1893, the case of a man who was exposed for the very brief period of three minutes to the inhalation of gas in an open trench. On immediate removal he was insensible; coma with repeated convulsions lasted for nine days when the man died. This case is also opposed to another assertion of Small (*loc. cit.*, p. 588) that when the onset of coma is sudden, it is less likely to be either profound or prolonged. It does not appear from my cases that the mode of onset of coma is of much prognostic significance. The following cases are cited in illustration:

Case 3.—Male. German, forty-five years old; became despondent through loss of work and, having complained all day of headache, put an open gas pipe in his mouth, and was found unconscious a few minutes after, by his wife. In the hospital he exhibited profound coma, a feeble, irregular pulse, and a chest full of large sonorous moist râles. Respiration was of Cheyne-Stokes type, and the exhaled breath smelled strongly of gas for twelve hours. The evacuations of urine and fæces were involuntary. The chest was cupped, phlebotomy was performed (℥viii) followed by infusion (c.c. 1,000). Slight improvement resulted, but profound coma persisted for four days, when the patient could be aroused to take nourishment. His maximum temperature was only 100.5°; pulse, 104; respiration, 24, and leucocytes, 10,400. On the eleventh day the patient was discharged cured, although the persistence of melancholia should remind one that in suicidal cases, melancholia during convalescence might be mistaken for a remaining symptom of poisoning.

This case is interesting on the following grounds: (*a*) The sudden onset of profound coma; (*b*) the predominance of coma over all other symptoms, notably the nearly normal pulse, respiration, and temperature; (*c*) the final recovery after four days of deep coma.

Cases 43, 44, 45, and 46 belonged to a series of five patients all sleeping in one room into which water-gas, containing 20 per cent. of carbon monoxid, escaped for about ten hours. All were equally exposed: one died after eight days, two recovered in four and five days respectively, and one remained either comatose or delirious and stupid for three weeks, with a continued fever, but without pneumonia; he was finally taken home, when nearly well. (The fifth patient was not brought to the hospital.)

E. H. Bartley states (Wood's "Reference Handbook of the Medical Sciences," Vol. II, p. 215) that "when entire unconsciousness has occurred recovery is very unusual." This is, to say the least, a pessimistic view, for of the 90 cases of this series in which coma was profound 73 resulted in recovery. In 39, or more than one-half of the non-fatal cases, coma lasted one day or longer, and in 12 more it lasted half a day (12 hours). Among the longest non-fatal coma records are the following: 1 case of 10 days' duration, 1 of 4 days; 4 of 3 days, and 4 of 2 days.

Rigors may be present, but more common are general muscular tremors and twitching or spasm, which latter may finally result in violent convulsive seizures and opisthotonos. Repeated convulsions have been known to last for days. In Hewetson's case they persisted for nine days; in some of my cases for three or four days. In eight cases they were very severe. One patient had convulsions on the third day for the first time, but she gave a history of epilepsy, and they were apparently of that origin. She recovered.

Rigidity of a part, or of all of the skeletal muscles, was very persistent in a half dozen cases, and in one it lasted in some degree for three weeks, and was often accompanied by twitching or convulsions. (Recovery). The major reflexes present considerable variation. In many cases they were normal, and when altered, in about equal number they were increased or diminished. During convalescence patients often complain of stiffness of the muscles and sometimes appear dazed when first attempting to walk.

A patient of Broadbent's (*British Medical Journal*, May 13, 1903) improved for ten days, when rapid muscular atrophy ensued, and the asthenia culminated in death on the nineteenth day.

Phlebotomy, followed by venous infusion of normal salt solution, should be performed in every case in which the patient is unconscious and the pulse is vigorous. Infusion alone should be performed in every unconscious case in which the pulse is too feeble to justify phlebotomy. If these operations are done at all they should be thorough. It is better to withdraw 15 or 18 ounces of blood than 8 or 10 whenever the pulse strength permits, and at least 1500 c.c. of saline solution should be infused. The latter process may be repeated upon the opposite arm, or hypodermoclysis and saline enemata may be given. The objection sometimes raised against saline infusion, that it may produce pulmonary œdema, is not sustained by the evidence of the series of 41 cases in which it was employed, for in no one of them did it give rise to the physical signs or the post-mortem finding of œdema of the lungs, but, on the contrary, often relieved this condition when already present. Whether the phlebotomy and infusion act by removing a small portion of the poison, by diluting the blood, affecting the vascular pressure, by the influence of the salt infused, by stimulating the formation of new red blood cells, or in some other manner, the clinical fact remains that these measures are beneficial. They do not immediately restore consciousness, but in the bedside notes of the cases herein reported it is almost invariably stated that immediately after infusion the pulse grew stronger, respiration was of better character, muscular twitching disappeared, rigidity lessened, and the general condition of the patient improved. Of course there are many cases in which a very large dose of the gas renders all curative efforts futile, but in a considerable proportion the improvement which follows phlebotomy and infusion ultimately results in recovery.

Pathological Findings.—In the succeeding twelve cases, in which autopsies were performed, I shall merely quote the records in so far as they concern the heart, lungs, and brain, as nothing distinctive was observed in the kidneys or any other organs. For these records I am indebted to the pathologists of the Presbyterian Hospital, and (for one case) to Dr. W. J. Elser.

Case 54.—*Heart* muscle pale and flabby; left

pleura adherent to thorax throughout; *lungs* on section both show congestion and œdema throughout; *brain* appears normal.

Case 86.—*Heart* presents lesions of chronic endocarditis and myocarditis; the mitral valve is irregularly thickened, and there are numerous calcareous vegetations on the aortic valve; *lungs* pale but otherwise normal; *brain*, a calcareous embolus is found lodged in the internal carotid artery, at the origin of the middle and anterior cerebral arteries. The lodgment of this embolus explains an attack of partial hæmiplegia which the patient had three months before death, and did not appear to be in any manner connected with the cause of death; the brain otherwise appeared normal.

Case 78.—*Heart* presents fibrous patches on the endocardium and fatty degeneration of the papillary muscles; *lungs*, the right lower lobe of the lung is congested and the left lung is œdematous anteriorly; areas of bronchopneumonia involve the right upper lobe and posterior part of the left lower lobe; the *brain* exhibits atheromatous nodules in the left middle cerebral artery, and congestion of the vessels of the pia, corpus callosum and corpus striatum.

Case 80.—*Heart* soft and flabby, but not dilated, filled with fluid and clotted blood; *lungs* are both slightly œdematous, otherwise normal; *brain*, evidence of chronic meningitis is present; the dura mater is adherent to the calvareum, and both meninges and brain substance are much congested; the lateral ventricles contain a small quantity of bloody serum.

Case 55.—*Heart* normal; *lungs:* left pleura presents patches of fibrous thickening near the base of the lung, and a few petechiæ over the posterior part of the left upper lobe, the latter is œdematous and congested; the left lower lobe is dark red and its posterior portion is atelectatic; the right pleura is here and there adherent, the right lung is emphasematous anteriorly, but posteriorly it is congested and œdematous, with areas of partial atelectasis; the *brain* substance, arachnoid and pia are all mod erately congested.

Case 56.—*Heart* muscle and pericardium are of a dark reddish or purple hue; the heart is otherwise normal; *lungs:* the left upper lobe of the lung is tuberculous, the left lower lobe is congested; the right lung shows areas of emphysema, congestion and bronchopneumonia; the *brain* substance and arachnoid are congested.

Case 57.—*Heart* normal, excepting slight atheroma of the coronary arteries; *lungs:* the entire pleura is everywhere adherent, and the left upper lobe of the lung presents a chronic miliary tuberculosis; miliary tubercles are also scattered throughout the right lung; congestion and œdema are absent; *brain* not examined.

Case 58.—*Heart* muscle flabby, but the organ is otherwise normal; the right *pleura* is somewhat adherent, the *lungs* are normal; *brain* not examined.

Case 59.—*Heart* normal; pericardium dry, but non-adherent; *lungs:* few petechiæ on entire pleura; posterior portion of left upper lobe of the lung is dark and somewhat atelectatic, right upper lobe is congested posteriorly, emphysematous anteriorly, right lower lobe somewhat atelectatic posteriorly; trachea and larynx are deeply congested; the *brain* is much congested throughout.

Case 85.—The *heart* muscle is pale and flabby, the left ventricle is slightly dilated; the *lungs* are both deeply congested, and show slight emphysema anteriorly; the pleura is adherent over the right upper lobe; *brain* not examined.

Case 60.—*Heart* shows advanced stage of chronic endocarditis with calcareous deposit in and vegetations upon the aortic cusps, a thickened mitral valve and retracted chordæ tendineæ; the heart muscle is pale and hypertrophied; the *lungs* are congested and œdematous and the pleura is adherent over the right upper lobe; the *brain* tissue appears normal but the cerebral vessels are highly atheromatous.

Case 61. The *heart* is slightly hypertrophied and filled with partially clotted dark red blood. The myocardium is of a pale red, somewhat cloudy appearance; in the coronary vessels and aortic arch is a moderate grade of atheroma; the valves are normal. The *lungs* present a moderate grade of congestion and œdema, and in the lower lobes are foci of aspiration pneumonia; the bronchi are congested and contain an abundant serous exudate; in the pleuræ on both sides are about 100 c.c. of clear serous fluid. The *brain* substance is soft and œdematous, the convolutions are flattened and the meninges congested; the ventricles contain much fluid; the anterior internal portion of the left ventricular nucleus, and the adjoining portion of the internal capsule exhibit an area of softeningabout three-quarters of an inch in diameter, which contains a number of minute capillary hemorrhages; the basilar vessels are normal.

[The notes of this autopsy were furnished by Dr. William J. Esler, from the clinic of Dr. G. L. Peabody, at the New York Hospital.]

It is of some interest to note that in no one of these twelve fatal cases was there entire absence of some serious chronic lesion in heart, lungs, or brain, despite the fact that many of the patients were young. Thus chronic endocarditis, myocarditis, tuberculosis, pleuritic adhesions, atheroma, chronic meningitis, etc., testify to the ill health and lowered vitality of a class of patients whom privation and physical suffering may have driven to suicide, or whom ignorance, stupidity, or alcoholism has led to fatal poisoning. The important conclusion seems justified that many of these patients might have survived the gas intoxication, had not either their respiratory, circulatory, or nervous mechanisms been already seriously undermined.

The Heart.—Among the twelve autopsies, in three the heart was normal, in three it is described as "pale and flabby," and in six there was evidence of either chronic endocarditis, myocarditis, or atheroma of the coronary vessels. Hence there is no constant appearance of the heart in gas poisoning. If this toxic agent caused death by direct paralysis of the heart, it might be expected to be uniformly pale and flabby and perhaps dilated, but the few cases in which these occurrences were noted are offset by others in which it appeared normal, or (as in Case 56) of a dark red color.

The Lungs.—It was a surprise to the writer that bronchopneumonia, or other definite pulmonary lesion, is not more constantly an outcome of fatal gas poisoning, but in only three of the twelve autopsies was bronchopneumonia observed. I have seen it in one other private case in which it followed complete recovery from the gas intoxication and ultimately proved fatal. Two other cases of this series presented normal lungs, and a third, lungs which were without congestion or œdema, having only a few miliary tubercles, hence it may be asserted that death from illuminating gas is not invariably due, if it ever is, to direct irritant action upon the lungs or bronchi after the manner of smoke or toxic vapors. The conditions which might be attributed to such action may be described as functional disturbances rather than organic changes, such are: (1) Congestion, complete (one case); (2) congestion and œdema, complete (three cases); congestion and

œdema in partial areas (five cases), in all eight cases; (3) atelectasis, partial (two cases); (4) emphysema, compensatory and partial (four cases). These four different conditions were found in varying degree and association in nine of the twelve cases examined, yet it is well known that all these appearances are common in the lungs of those dying slowly from profound toxic influences affecting the blood, the circulation or the central nervous system, without reference to any specific pulmonary irritation whatever, and such would appear to be the fact in illuminating gas poisoning.

The Brain.—Of the nine cases in which the brain was examined, six presented marked congestion of the brain substance, pia and arachnoid; in one of these cases, however, there was evidence of a chronic meningitis; in the three remaining cases the brain and its membranes seemed normal. It would thus appear that cerebral congestion is a common result of poisoning from illuminating gas, occurring in the series of autopsies cited, six times out of nine. To what extent this may be a cause of death is difficult to determine, but there can be little doubt that it is often a contributing factor, although not invariably present. In three of the cases there were marked changes in the corpus callosum, corpus striatum or ventricles, consisting of such conditions as softening, congestion, and hemorrhages.

These appearances, which have also been reported by other writers, are of the greatest interest. Some years ago Klebs pointed out the fact that carbonic oxide poisoning is capable of producing enormous distention of the cerebral arteries, and in 1893 Alexander Kolisko[16] referred to this distention of the central terminal branches of the anterior cerebral artery as the seat of thrombosis following distention, and giving rise to the softening of the internal capsule, and especially of the lenticular nucleus, which has been often observed. He states that he has seen several such cases resulting from CO poisoning, and refers to two more observed by Polcher. Another interesting case of softening of the internal capsule and lenticular nucleus was reported by Broadbent,[17] also in 1893. Schaeffer[18] has reported two fatal cases in which he found softening of the brain, cord, and peripheral nerves.

Von Sölder[19] reported the case of a man, forty-one years of age, who died four months after gas inhalation. At autopsy were found hyaline and fatty degeneration of the skeletal muscles, atrophy of peripheral nerves, and degeneration of the anterior horns in the cervical and dorsal cord. J. W. Runeberg[20] reported two fatal cases with extensive softening in the lenticular nucleus.

Summary.—From a study of the foregoing cases the following conclusions regarding comatose cases of illuminating gas poisoning may be drawn:

1. Leucocytosis is both high and persistent, rising in many cases above 18,000, and in a few fatal cases as high as 50,000. A differential leucocyte count shows preponderance of the polymorphonuclear cells. A high degree of leucocytosis is a very unfavorable prognostic symptom.

2. Elevation of temperature is observed in nearly all cases. The fever is usually moderate and of very irregular type. In many cases a subnormal temperature precedes the elevation, and it is often observed also in convalescence. The pulse is disproportionately rapid, as compared with the temperature.

3. The nervous symptoms are both varied and inconstant. Convulsions occur in about 7 per cent. of all cases and muscular rigidity in a slightly larger proportion. The reflexes and pupil symptoms show great variability. The coma bears no definite relation to the intensity or duration of the fever. Coma lasting four or five days is not invariably fatal. In the series of ninety comatose cases only seventeen cases, or 18.8 per cent., were fatal.

4. The results of combined phlebotomy and saline infusion justify the prompt and thorough employment of these measures.

5. Pneumonia is an infrequent complication, and in a large percentage of fatal cases the cause of death may be referred to cerebral lesions, such as congestion of the meninges and brain substance, hemorrhage of the cerebral capillaries, or hemorrhage into and softening of the internal capsule, lenticular nucleus, and adjacent structures.

THE DIAGNOSIS OF TYPHOID PERFORATION AND ITS TREATMENT BY OPERATION.*

By CHARLES A. ELSBERG, M.D.,
NEW YORK.
ADJUNCT ATTENDING SURGEON TO THE MT. SINAI HOSPITAL, NEW YORK.

It is now generally recognized that—in spite of the fact that an occasional patient will ecover without surgical interference—operative treatment is indicated in every case of perforation of the intestine in the course of typhoid fever as soon as the diagnosis has been made. The main questions that confront the medical man are (1) on what can we base the diagnosis of perforation and the indications for operation, and (2) in what cases are we justified in recommending surgical interference when the diagnosis is still in doubt. Operative interference for suspicious symptoms is a course that has been declared justifiable by most writers on this subject, among whom may be mentioned Finney,[1] Cushing,[2] Herringham and Bowlby,[3] Shattuck, Warren and Cobb,[4] and many others. Inasmuch as the dangers from a small exploratory incision are much smaller than those of a perforation of the intestine, this

*Read at the meeting of the Surgical Section of the New York Academy of Medicine. This paper is based upon four cases of perforation of the intestine in the course of typhoid fever that the writer has operated upon in the Second Surgical Service at Mt. Sinai Hospital (Dr. Howard Lilienthal, Attending Surgeon), and upon the occasional observation of eleven others which were operated upon by others of the surgical staff of the hospital during the past three years. Of these fifteen cases, five were operated upon in the First Surgical Service of Dr. A. G. Gerster during 1901 and 1902, and have been already published in the Mt. Sinai Hospital Reports for those years; ten were operated upon in the Second Surgical Service from 1901 to 1903. The cases that occurred in 1901–1902 are published in the annual hospital reports for those years; those from the year 1903 have not yet appeared in print, and will form part of a report on the surgery of the intestines in the Second Surgical Service of Dr. Lilienthal for the past four years, which will be published elsewhere.

course would certainly seem the correct one. As I shall mention later, however, delay is advisable in some of the cases.

There has been much discussion as to what is meant by the term "symptoms of perforation," and there is still little unanimity of opinion on this question. The attempt to distinguish between the symptoms of perforation and those of the resulting peritonitis is in very many cases impossible. The only symptoms of perforation, *per se*, that I can conceive of are, perhaps, sudden abdominal pain and the presence of free gas in the abdominal cavity. Sudden abdominal pain occurs fairly often during the course of typhoid fever, and localized pain and distention of the abdomen are very frequent in this disease, as has been ably shown by McCrae.[5] The presence of free gas in the peritoneal cavity—if it can be clearly demonstrated—is almost pathognomonic of perforation. Unfortunately, however, it is often difficult, if not impossible, to determine with certainty that the gas in the abdominal cavity is free, and in the second place, in many cases of perforation of the intestine there is no free gas. In the large majority of cases the diagnosis of perforation is made from the symptoms of an affection of the peritoneum which has been caused by the perforation and not from any symptoms concomitant with and caused by the perforative process. This is the view now adopted by Osler.[6]

By this I do not mean to say that there is not anything characteristic in the onset, and more especially in the symptoms of the peritonitis, but that, in the large majority of instances, we are really describing the early symptoms of peritonitis due to the perforation, rather than the symptoms of the perforation itself. In what follows, however, the term symptoms of perforation will be used for the sake of simplicity of expression, instead of the longer term symptoms of peritonitis due to a perforation.

I. *Some Diagnostic Features of Typhoid Perforation.*—It is always important to obtain from the physician in attendance data as to the amount of tympanites, pain, tenderness, etc., that the case presented during the entire course of the typhoid fever. We have to learn from the internist regarding the appearance and changes in the symptoms and signs from the beginning of the symptoms of perforation. In the cases on which this paper is based, there was usually the history of the patients having suddenly complained of abdominal pain, or of the more or less sudden appearance of signs of increase of the existing pain and tenderness. Thereafter a number of signs and symptoms appeared and progressed until the diagnosis of intestinal perforation could be made with certainty. At this time the patients had more or less increase in the pulse and respiration, some were in collapse, others not so, the abdomen was tender, distended, and rigid to a varying degree, there were the signs of free fluid and sometimes of free gas in the peritoneal cavity. Collapse does not occur as often as one would expect in these patients, and it would seem as if the degree of collapse was dependent more upon the virulence of the peritoneal infection than upon the size of the perforation or the amount of intestinal contents that has escaped. Thus of the fifteen cases that form the basis of this paper, only four were in collapse when the diagnosis of perforation was considered sufficiently certain to indicate operative interference. In almost all of the patients the general condition became steadily worse up to the time of operation, in most of them the condition was very poor, but only four were in utter collapse at the time of the laparotomy.

The distention of the abdomen varied much in the fifteen cases. In six cases the distention was very marked, in eight the distention was only slight or moderate, in one case there was no distention. It is rare that the abdominal distention is due to the escape of a large quantity of gas from the perforated bowel. The gas is usually within the intestine, very often the amount of abdominal distention is directly proportional to the degree and extent of the peritoneal inflammation.

Diminution in the area of liver dulness has been a valuable diagnostic aid to us in our cases. There was a greater or lesser diminution in the area of liver dulness in fourteen of the fifteen patients. In a considerable number of cases this diminution is due more to the intestinal distention than to the presence of free gas in the peritoneal cavity. A distended transverse colon or small intestine may get in front of the liver or rotate it on its transverse axis, and in that way cause a diminution in the area of normal liver dulness. Hence the value of attempting to percuss out the colon very carefully and of knowing when the patient's bowels have last moved and what amount of flatus was passed at that time.

Abdominal pain and tenderness are usually most marked on the right side of the abdomen, although the entire abdomen is often tender in these patients. In six cases of those on which this paper is based, all parts of the abdomen were equally tender; in seven the tenderness was most marked on the right side and lower part of the abdomen; in two cases the greatest amount of tenderness was in the left iliac region.

In sixteen patients there were the signs of free fluid in the abdomen—movable dulness in the flanks or fluid wave or both.

Although the normal area of liver dulness was considerably diminished in fourteen patients, as has been already mentioned, free gas could be demonstrated in only five of these. The presence of movable tympany in the flanks with concomitant changes in the area of liver dulness is characteristic of free gas in the abdominal cavity. The patients are usually examined for the evidences of free gas by turning them first on one side and then on the other and percussing both flanks in these positions. It is advisable to move these patients as little as possible, however, and a very thorough examination for free gas is therefore often not made. I have found it a very useful and valuable expedient, when examining for free gas, to have the head end of the patient's bed raised up very high by an orderly and then to percuss the upper and lower parts of the abdomen very carefully; then to have the head end of the bed lowered and the foot end raised and then to percuss the abdomen again, and to observe the changes that have taken place. I have found the method a very useful one for the demonstration of free gas in the peritoneal cavity, without moving the patient from his dorsal position.

The temperature changes in the cases did not seem to present anything characteristic, the temperature was sometimes high and at other times low when the first symptoms referable to the peritoneum were noted.

In about one-half of the cases there was a leucocytosis of between 11,000 and 18,000, in the other patients there were less than 8,000 white cells to the cubic millimeter. Regarding the value of leucocytosis, we have come to the same conclusion as many other recent writers—that the leucocytosis has but a limited value. The presence of a leucocytosis can be used only with circumspection as a diagnostic symptom, while its absence does not at all exclude the possibility of a perforation.

II. *The Indications for Operative Interference.*—In most of the cases referred to in this paper, the diagnosis of perforation of the bowel could be made with almost certainty within four to twelve hours from the appearance of the first suspicious symptom. As most of the patients were transferred to the surgical side of the hospital from the medical side, the surgeon was asked to see the cases at a very early stage, but there was often considerable delay before permission for the surgical interference could be obtained. The diagnosis was usually first made by the house staff of the hospital, who were on the spot to watch the symptoms from their beginning, and much credit should be given these gentlemen for the care with which they studied the cases. During the past three years not a single patient has been operated upon at our hospital for typhoid perforation in which the perforation was not present. One case in which all the symptoms and signs which are considered characteristic of perforation were present, and in which permission for the operation was refused, recovered without operative interference; two patients died without operative interference, as in both the condition was so bad that surgical interference of any kind was considered contraindicated.

If perforation of the bowel in the course of typhoid fever is considered a surgical complication—and there is very little doubt that it should be considered so—then immediate surgical interference should follow as soon as the diagnosis has been made. These patients bear the operative interference remarkably well if only the manipulations are rapidly done; and one is soon convinced of the correctness of the statement made by Cushing[7] that the "diagnosis once having been made, nothing short of a moribund condition of the patient is a contraindication to immediate operation."

In the cases in which the diagnosis is probable, especially if the general condition of the patient is becoming steadily worse, it is advisable to make a small exploratory incision. The operation can be completed in less than ten minutes, and, if the peritoneal cavity should be found normal, the abdomen can be quickly closed again, and the patient be sent back to his bed with a good expectation that his general condition will be little or not at all made worse by the operation.

It is more difficult, however, to determine if an operation should be done when the symptoms make one suspicious that a perforation may have taken place, but the symptoms are not clear. Of these cases, a number really have a perforation, and in them a policy of delay would not be the one in the best interests of the patient. From our experience with typhoid perforation during the last three years we have been forced to conclude that when the symptoms have been of at least twelve hours' duration and the signs and symptoms point more to a perforation than to anything else, especially if the patient's general condition is growing steadily worse, the operation is a justifiable one.

It need hardly be mentioned that if the signs of peritonitis are sufficiently marked to indicate operative interference, no matter what the diagnosis, delay would be inexcusable.

If, however, the symptoms have existed for more than twenty-four hours, the patient's general condition has remained good, and the diagnosis is still in doubt, perhaps because the patient has only come under observation at this time, the surgeon is justified in advising a few hours' delay if the case can be carefully watched. If a case of this kind has a perforation, it is probable that the affected loop of intestine is walled off by adhesions from the general peritoneal cavity. Delay in these late cases should, however, only be advised after the most careful consideration of the case from every aspect. If the diagnosis is fairly sure, it would be just as wrong to wait for adhesions to form in these cases as in a case of acute appendicitis. The danger of an ill-timed delay is very great, and it is better to open an abdomen in rare instances and to find nothing than to delay too long where early operation is called for. With thorough observation and careful individualization it is probable that mistakes on one side or the other will be very few.

About six weeks ago a patient was admitted into the hospital with symptoms of more than twenty-four hours' standing of perforation of the intestine in the course of typhoid fever, in which Dr. Lilienthal advised delay on account of the good general condition of the patient, the duration of the symptoms, and the lack of certainty of the diagnosis. Twenty-four hours later, however, the signs of peritonitis became more marked, immediate operation was done, and a large, well-walled-off abscess opened. A fecal fistula became established, but closed after several weeks, and the patient is now convalescent.

II. *Some of the Conditions Found at Operation.*—In ten of the fifteen cases the abdomen contained seropurulent fluid in considerable quantities, and there were no adhesions between the coils of intestine or, at the most, only a few flakes of fibrin on the intestines. In all of these cases the operation was done in less than twenty hours from the beginning of the symptoms of perforation. In five patients there were adhesions in considerable number between the coils of gut and the omentum, and in these cases the perforated loop of intestine was usually walled off by the adhesions from the remainder of the peritoneal cavity, and there was a collection of seropurulent fluid or pus in this walled-off cavity. In these five cases the length of time between the beginning of the symptoms of perforation and the operation was 36, 18, 24, 6, and 48 hours, respectively. The foregoing figures show that adhesions are not very frequent in the early stages of typhoid perforation. Whether this want of the tendency to form adhesions is due to the low percentage of the fibrin factors in the blood serum of these patients, or to something in the intestinal contents (toxin? typhoid bacillus?) which has an influence in preventing the formation of adhesions, it is impossible to say. Many authors have mentioned the fact that adhesions are rare in the early stages of perforative peritonitis in typhoid fever without attempting to give any explanation for it. (Cushing,[7] McCrae and Mitchell,[8] Russel,[9] Fix and Gaillard,[10] etc.) Sometimes the perforation is closed by fibrin, or by an adhesion of omentum or neighboring coil of intestine, but more often it opens free into the peritoneal cavity, so that when the perforation is exposed, fecal material is to be seen to be escaping from it.

In six of the fifteen cases the abdominal cavity contained free gas, in five of which the free gas was demonstrable before the operation. As has been already mentioned, the presence of free gas in the peritoneal cavity makes the diagnosis certain.

Deep ulcerated Peyer's patches, which have not yet perforated, can be plainly seen through the peritoneal coat of the bowel as deep red, round, or oval areas. If the peritoneum which forms their base has lost its normal lustre and feels thick and infiltrated, the ulcers must be considered on the verge of perforation. In two of my cases and in several of those operated upon by colleagues at the hospital, there were suspicious areas of this kind. Sometimes these suspicious spots are so numerous

that they occupy the greater part of the lower one to two feet of the ilium with, perhaps, the appendix vermiformis and part of the cæcum and ascending colon, so that it is almost impossible to suture over all of them without causing an extensive and too great a narrowing of the lumen of the bowel. This condition was present in one of my cases in which I sewed over only the very worst patches, four in number, and had the misfortune to lose the patient from the perforation of still another ulcer. The post-mortem examination in this case showed that the lower foot of the ileum was filled with large and deep ulcers. The ideal method of treatment in these cases would be the resection of the affected loop of intestine—a procedure which is, however, too dangerous, and which would no doubt cause so much shock that few of the patients would long survive it.

IV. *The Manner in Which the Patients Stand the Operative Interference.*—One would expect that patients—the most of whom are already exhausted by their long and severe disease—would bear the operative interference badly. Fortunately, however, this is very often not the case, and, if the operative manipulations are done with rapidity, the patients seem often to be in better condition at the end of the laparotomy than they were at its beginning. In some way, the removal of the toxic material from the peritoneal cavity has an immediate beneficial effect upon the general condition. This improvement may be due in part to the hot saline irrigation of the peritoneal cavity, which acts not only as a cleansing agent but also as a powerful stimulant—an internal infusion. It may also be due in part to the morphine which is often given to the patients just before the operation. It must be remembered in this connection, however, that the same methods are usually adopted by us during operations for other perforative conditions of the gastrointestinal tract. But in the latter I have never seen such marked improvement immediately after the operative interference. Of the writer's four cases, three were in distinctly better condition when the operation was concluded than before it was begun. The same has been the case in many of the patients operated upon by others at Mt. Sinai Hospital and in many of the cases reported in the literature of the subject. In the cases with a fatal outcome, most of the patients did not die from shock a few hours after the operation, but they died a number of days later from the infection of the peritoneal cavity due to the perforation. Several patients recovered from the laparotomy but died after several weeks from their typhoid fever. The remarkable manner in which a large number of these patients stand the operative interference has been already commented upon by a number of writers, especially by Cushing and Finney of Johns Hopkins. An important condition for success, as I have just mentioned, is that the operative manipulations be rapidly done, with as little exposure of the intestines as possible.

V. *The Course of the Disease after the Operation.*—As is well known, perforation in typhoid fever occurs most often during the course of the third to fourth week of the disease or during a relapse, at a time when the fever is usually still high. In three of the patients that I have operated upon, and in several of the cases operated upon by colleagues at our hospital, there was within twelve to eighteen hours after the operation a sudden fall of the temperature to the normal or near the normal, followed later by a rise, but the regular course of the typhoid temperature seemed to have been broken. The writer has gained the impression that such a fall of temperature during the first twenty-four hours after the operation has considerable prognostic significance, inasmuch as four of the five patients that recovered had this drop of temperature. It was present only in one patient in whom the disease ended fatally, and that was a case in which the patient died in sudden collapse from a second perforation (see Case IV at the end of this article). In this connection it is of interest that Hutchinson (*Philadelphia Medical Journal*, January 17, 1903) gives an account of three cases in which no perforation was found at operation and the abdomen had been flushed with saline solution, in each of which there was a distinct drop in the temperature for thirty-six hours, after which the typhoid fever continued its course and the patients recovered.

In one of my cases the temperature again rose, due to the appearance of numerous furuncles and abscesses all over the body; in a second case, after ten days of normal temperature, the patient had a severe and prolonged relapse with high temperatures and a very rapid pulse, but he recovered.*

In the patients that recovered, the abdominal signs disappeared with considerable rapidity; at the end of twenty-four to forty-eight hours, the abdomen had become much less distended and tender, and in four to five days practically all of the abdominal symptoms, except those due to the wound in the abdominal wall, had disappeared.

Healing was not essentially different from that after laparotomy for perforative peritonitis from other causes. The wound in the abdominal wall should be drained, as otherwise it is very apt to become infected.

VII. *Some Details Regarding the Operative Manipulations Which Are of Interest.*—Rapidity is a *sine qua non* for success in operations for typhoid perforation. In less than twenty minutes' time it is usually possible to open the abdomen on the right side, find the perforation and suture it, examine four to six feet of the lower ileum, beginning at the ileocæcal junction, suture over any areas that seem to be in danger of perforating, wash out the peritoneal cavity with hot saline solution, drain the peritoneal suture line, and close the remainder of the incision in the abdominal wall by an appropriate suture. The duration of the operation in the writer's cases was 11, 18, 14, and 23 minutes respectively. The abdominal incision should preferably be made along the outer side of the right rectus muscle or through its fibers, as the lesion will most often be found on the right side of the abdominal cavity, unless the physical signs should point to some other part of the abdomen. The incision should be a liberal one from the very beginning. As soon as the peritoneal cavity has been opened, one must look for the cæcum and ileocæcal junction, and when this part of the bowel has been exposed, pull into the wound the most prominent loop of small intestine which lies against it. In a considerable number of the cases, this loop will be found to be the affected one and the perforation thus be most quickly found. If there is no one loop that is particularly prominent, one must begin the examination of the ileum from the ileocæcal junction. As soon as the perforated ulcer has been found, the opening should be closed by a double layer of Lembert sutures passed in the long axis of the bowel, so that they will cause a minimum amount of narrowing of the lumen of the intestine. If the perforation of the bowel wall is so large or the infiltration so extensive that simple suture is impossible, one of two procedures can be followed—

*The recovery of this patient was in no little part due to the very careful watching and treatment of the house physician, Dr. Kremer.

either a portion of the omentum can be sewed over the opening, or the affected loop of intestine can be anchored in the wound by a few sutures, and a fecal fistula thus established. Escher[11] has recently recommended that the perforation should never be sutured, but that the loop of bowel should be anchored in the abdominal wound and the bowel drained. Escher claims that the operation can thus be done with great rapidity, and that the drainage of the bowel prevents paralytic ileus and exerts a favorable effect upon the peritonitis. It is preferable, however, to close the perforation, unless it be too large or the surrounding bowel wall too much diseased. In the latter condition the method of Escher is surely preferable to resection of the bowel.

If there is any doubt that the intestinal sutures will hold, it might be advisable to keep the loop near the wound by fixing its mesentery or the bowel itself to the abdominal wall with a few sutures.

Any ulcers that seem to be in danger of perforating should be just as carefully sewn over as the perforated one. If there are a large number of these dangerous ulcers in the lower ileum, it is advisable to wall off the affected loop of gut from the peritoneal cavity by a small gauze packing on each side of it, and thus guard against the danger to the peritoneal cavity from a possible later perforation.

Wherever sutures have been applied to the intestinal wall, it is a good plan to rub a little iodoform powder over the suture line—through the irritant qualities of the iodoform the adhesive process is hastened.

Since the publication of the writer's last paper on perforation of the intestine in the course of typhoid fever, he has been led to change his views on the subject of irrigation of the peritoneal cavity. Although we have to depend to a great extent upon the absorptive powers of the peritoneum, absorption can be hastened and aided by irrigation of the cavity with isotonic 0.9 per cent. saline solution. Aside from the fact that by this irrigation considerable toxic material is removed, it acts also as a powerful stimulant, and this function of the irrigating solution should not be underestimated. One has only to note the immediate improvement in the patient's condition in a few cases in order to become convinced of its value.

After a thorough irrigation, the smaller the drain that is inserted into the abdomen the better. It is now well known that drainage of the general peritoneal cavity can seldom, if ever, be accomplished. It will generally suffice to pass a small strip of gauze or a cigarette drain down to the suture line in the intestine or underneath the sutures in the parietal peritoneum, and then to close the greater part of the abdominal incision.

In the cases in which the perforation in the wall of the bowel is walled off from the general peritoneal cavity by adhesions and lies in the bottom of an abscess cavity, it is advisable to do nothing more than to open the abscess and drain it, leaving the perforation in the wall of the intestine to take care of itself. The fecal fistula which usually becomes established will often close of itself, as it is situated in the lowermost part of the ileum, otherwise a second operation may be necessary later on to close it.

Many writers recommend that operations for typhoid perforation had best be done under local anæsthesia. However, the writer would agree with those who prefer a general anæsthesia. I believe that a fair-sized dose of morphine, followed by a light chloroform anæsthesia, is preferable in most cases. From my experience in abdominal surgery under local anæsthesia, I have learned that in most cases the handling of the small intestine and the straining of the patient while the abdomen is being washed out with saline solution contributes more to shock than a light chloroform anæsthesia, aside from the fact that under general anæsthesia the necessary manipulations can be more quickly accomplished.

The after-treatment need differ in no way from that after laparotomy for other conditions, with the exception that the general feeding must be that of a patient with typhoid fever.

Case I.—Female, six and a half years of age, transferred from the service of Dr. Koplik. Perforation on lower ileum on thirty-third day of severe typhoid. Before operation, temperature, 104.4; pulse, 180; respiration, 40. Collapse very marked. Laparotomy and suture of perforation sixteen hours after first symptom. Seropurulent peritonitis, free gas in peritoneal cavity. Duration of operation, eleven minutes. Convalescence delayed by furunculosis and multiple abscesses; recovery.[12]

Case II.—Male, eighteen years of age, transferred from the medical service and operated upon September 21, 1903. Perforation in lower ileum in fifth week of disease. Laparotomy and suture of perforation and of one area on the verge of perforation. Fæces and free gas in peritoneal cavity. Duration of operation, eighteen minutes. After ten days of normal temperature, severe relapse with high temperatures and very rapid pulse; recovery.

Case III.—Male, nine years of age, admitted to the hospital and operated upon on August 6, 1903, in the third week of typhoid fever, with symptoms of general peritonitis of about twenty hours' standing. Patient's condition very poor, he had to be infused upon the operating table. Laparotomy with removal of appendix and suture of perforation in lower ileum; seropurulent peritonitis. Duration of operation, fourteen minutes; recovery.

Case IV.—Female, nine years of age, transferred from the children's service of Dr. Koplik and operated upon September 30, 1903. Patient in very poor condition. Perforation in lower ileum on twenty-seventh day of severe typhoid fever. Laparotomy and suture of perforation about eight hours after first symptom; suture of three suspicious areas; fluid and fæces in general peritoneal cavity. Duration of operation, twenty-three minutes. After eighteen hours, condition of patient fairly good; no vomiting, abdomen more soft and not very tender; pulse 130 and of good quality. At expiration of twenty-second hour, sudden change in condition; collapse, death. The post-mortem examination showed that there was a second perforation between two of the sutured areas; the entire lower twelve inches of the ileum was filled with numerous large and deep ulcers; large amount of fecal matter in peritoneal cavity.

A METHOD OF SECURING FIXATION AND HARDENING OF THE CENTRAL NERVOUS SYSTEM BEFORE THE AUTOPSY.*

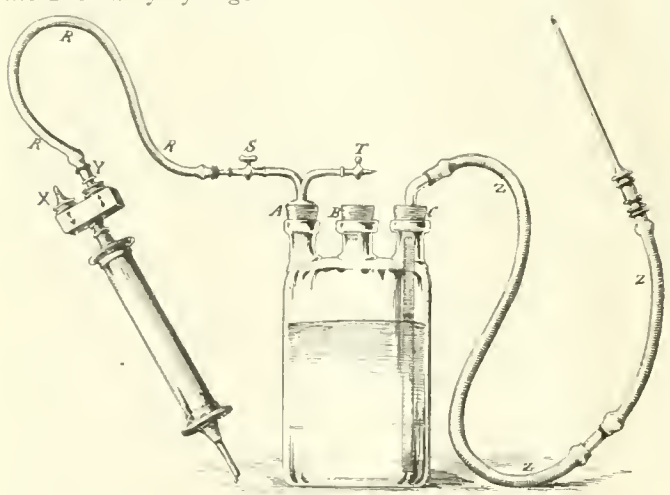
By B. ONUF (ONUFROWICZ), M.D.,
*PATHOLOGIST TO THE CRAIG COLONY, SONYEA, N. Y.

WHETHER the method herein described is new I do not know. It was new to me and it is certainly not generally known, otherwise the complaint of the inability to preserve the central nervous system within a few hours after death, consequently the impossibility of studying the finer structural changes in a given case, would not be heard so often.

The method is comparable in its simplicity to the egg of Columbus. The procedure consists in injecting as soon as possible after death a strong solution (12 per cent.) of formalin, first by lumbar puncture, then through the foramen magnum. The former hardens the spinal cord, the latter the brain. By use of a T branching tube, both injections can be combined in *one* act.

The details of the procedure may be varied according to necessity and further experience.

My first attempt, which proved surprisingly successful, was made with an aspiration needle and the Dieulafoy syringe.



Since then I have learned to use a Davidson ball syringe with equal success. It is known that the pump of the Dieulafoy syringe can be used in two ways, according to the manner in which it is connected, *i.e.* either for exhausting the air or for compressing it. In this procedure it is used for compressing the air.

The subjoined illustration shows the manner in which the apparatus is put together. It is convenient for the purpose to use a bottle with three mouths. This bottle is filled with the injection fluid. Mouth C has a rubber stop through the bore of which passes a glass tube down to the bottom of the vessel. At its upper end this glass tube is connected with the rubber tube ZZZ, preferably non-collapsible, to which is attached the aspiration needle. The latter attachment is by metal contact only, as is the case with many hypodermic needles which fit the barrel of the syringe by contact only instead of by a thread. Such an arrangement has the advantage of being easily detachable.

Mouth B is closed with a common cork or rubber stopper. It can be used for refilling the bottle when the fluid is almost exhausted without disturbing the other arrangements.

Mouth A has a rubber or cork stopper through the bore of which passes a T-shaped tube with which, by means of a thick-walled rubber tube RRR (preferably non-collapsible), the Dieulafoy syringe is connected. Stop-cocks of this T-shaped tube has to be kept open; stop-cock T of the same tube has to be kept closed. It hardly needs mentioning that the tube passing through the bore of the stopper of mouth A must not go down deep enough to reach the fluid. In other words, the bottle must not be filled so high as to have this tube immerged in the fluid.

The Dieulafoy aspiration syringe has two outlets, X and Y. If the rubber tube RRR is connected with outlet X, the action of the pump will exhaust the air in the bottle. If the rubber tube RRR is connected with the outlet Y of the pump, the action of the latter will, on the contrary, compress the air in the bottle.

The manner of required connection (namely, for compression) is indicated by arrows on the syringe. Moreover, a few trials will very soon show whether the pump is arranged for compression or for exhaustion.

After the apparatus has been put together in working order, one proceeds as follows:

The aspiration needle is detached from tube ZZZ and is introduced into the dural sac in the same manner and locality as in lumbar puncture. In doing so it is advisable to put the corpse into a sitting or semi-inclined position so as to let the cerebrospinal fluid accumulate in the lowest portion of the dural sac.

A trocaris preferable to a needle because the latter is apt to become obstructed by fat. There may or may not be an escape of fluid from the needle if the puncture is successful. The real test of the success lies in the result of the pumping, *i. e.* whether, when the pumping is started, the level of the fluid in the bottle is lowered.

After the needle, or trocar, has been introduced with apparent success, the pump is put in action, causing a compression of the air in the bottle ABC, pressing the fluid into the glass tube passing through C, and thence into the rubber tube ZZ. The pumping is continued until the fluid spurts out in a continuous stream from tube ZZ. At this moment, tube ZZ is quickly attached to the aspiration needle and the pumping is then continued. If the experiment was successful, the level of the fluid will now become lowered in the bottle. In case of doubt a mark designating the upper level of the fluid will soon show us whether this level is becoming lower or not. If it does not sink, this means either that the needle, or trocar, has not reached the spinal canal, or that the needle is obstructed by fat and other material. In such case tube ZZZ has to be detached and a wire is passed through the needle. If this is unsuccessful, the needle must be withdrawn and introduced a second time.

I may here add that my experiment succeeded only after I had introduced the needle for the third time.

The question now arises how long to continue pumping. My experience is that, after a time, the fluid sinks very slowly and the pumping becomes very difficult. Moreover, air is heard sizzling out around the corks or around the tubes passing through the corks, and from time to time the corks are forced out of the mouths. This is about the time to cease, and this forcing out of the corks serves as a safety valve, preventing, in all probability, the pressure of the injection fluid on the cord from becoming so high as to injure the tissues.

The idea is first to fill the entire dural sac with fluid and after that the whole spinal canal, into which the fluid will naturally ooze when the dural sac has become entirely filled.

*From the Pathological Laboratory of the Craig Colony for Epileptics, Sonyea, N. Y.

One next proceeds to harden the brain. The needle, or the trocar, is introduced into the fourth ventricle, at least that is the aim. The skull is palpated to locate approximately the foramen magnum, then the needle is tentatively introduced in the neighborhood of the foramen magnum and in a direction presumably parallel to the floor of the fourth ventricle. If it strikes bone, it will be rather easy to say whether such is the occipital bone or the spinous process of one of the upper cervical vertebræ. On the whole, it is better at first to strike too high, *i.e.* against the occipital bone. In such case the needle is taken out again and introduced a little lower down. One can thus gradually feel his way until he strikes just inward of the dorsal margin of the foramen magnum. The needle is then pushed deeply enough to enter the fourth ventricle, not deep enough, of course, to injure the cerebellum or oblongata. Whether the needle really needs to enter the fourth ventricle I do not know. Indeed it seems hardly necessary since the foramen Magendie gives sufficient means of communication between the ventricle and the surface of the cerebrum and cerebellum, so that, if only the subdural or subarachnoid space is entered, the fluid should have a good chance of being distributed over the surface of the cerebrum and cerebellum as well as to the ventricles.

The particulars will have to be learned by experience. Injury to the adjacent parts, cerebellum and oblongata, should of course be avoided. In my case neither of these structures showed any evidence of injury; but choosing between two evils, injury of the cerebellum would, on the whole, seem less harmful, special cases excepted, than injury of the oblongata. By keeping well in the median line, injury to both these parts can probably be prevented. If the needle should enter into the brain substance, this would soon be shown by the failure of pressing the fluid in, after the needle has been reconnected with the pumping apparatus and the pumping commenced. In case of success, the level of the fluid in the bottle will soon become visibly lower. As to the quantity of fluid to be used, I may say that, in my first attempt, about one-half pint was introduced into the brain and about four ounces into the vertebral canal.

Whether it is necessary to use a Dieulafoy aspiration, or rather compression, syringe for the injection, I cannot tell. As I have mentioned already, the same results may be obtained with the much cheaper Davidson syringe or with a similar ball syringe, in which case the bottle described can be done away with. Let me also repeat here, that by the use of a T branching tube, one end of which is connected with the pumping apparatus, the second end with the aspiration needle, passing into the lumbar sac, and the third end, with the needle passing into the forameg mannum, the two injectors, *i.e.* that into the ducal sac of the spinal cord, and that through the foramen magnum, can be combined in *one* procedure, thus saving time and equalizing the pressure of the fluid.

I shall now relate the results of the injection in our first case, which was made about one hour after death. First, however, let me mention that the body was then placed in the ice-box in usual position, *i.e.* lying on the back. This is, of course, the most common position, but there is a particular reason for mentioning it, as will be seen later.

The autopsy was made forty-three hours after death, the body being left meanwhile in the ice-box. The peculiarity was then noticed that the fat of the abdominal wall was of an abnormally firm, waxlike consistency and of a dark, dirty brown-gray color, while that of the thoracic wall had the usual appearance and consistency. On opening the abdomen, the fat of the mesentery in the lower portion of the abdomen was found to have the same peculiarity as that of the abdominal wall. I suspected that this was due to the effect of the formalin.

Further examination showed that a great portion of the liver also had a peculiar appearance, and here there was no doubt that such was due to the effect of the formalin, since the tissue in some parts looked whitish and was so hard that no other explanation was possible. I then felt certain that the peculiar fat referred to was due to the same cause.

First I was at a loss to account for this fact, but it now seems clear enough. It is natural to assume that, after the vertebral canal became filled with the injection fluid, it began to penetrate through the foramina intervertebralia into the surrounding tissues. It should be added, however, that the lungs, heart, spleen, pancreas, and kidneys showed no formalin effects, which is of value to know, as it shows that the spinal cord and brain may be preliminarily hardened without diminishing the value of an ordinary autopsy, to be made later on.

As to the effect of the injection on the spinal cord and brain, it surpassed my most sanguine expectations. The spinal cord was completely hardened in its entire length and thickness, as shown on a transverse section made through the middle dorsal region and as shown by its hard consistency through the entire length.

The brain also was, to all appearance, more or less hardened throughout. It showed the same elastic hardness which a brain shows after injection of a 10-per-cent. solution of formalin into the aorta (with tying off of the thoracic aorta), as practised by Drs. Adolf Meyer and Dunlap at the Pathological Institute of the New York State Hospitals. Twenty-four hours after removal of the brain the Meynert section was performed, *i.e.* the pallium (hemispheres) was separated from the rest of the brain. It was then shown that the formalin had penetrated everywhere. The hemispheres were found hardened in their whole thickness. The basal ganglia were also hardened, although in varying degree—the caudate nucleus less than the thalamus; but all parts showed the effects of the formalin. An absolute hardening of all parts could, of course, not be expected; but the important fact was noticed that no part showed any post-mortem decomposition, *i.e.* softening and putrefaction. Without the formalin such changes could have been expected with certainty, in view of the fact that the autopsy was performed forty-three hours after death, even although the body was in the ice-box all this time.

However, the most valid proof and most delicate test of the preserving and fixing value of the method was given in its influence on the neuroglia. That this tissue suffers very quickly through post-mortem disintegration is known to everybody familiar with it, and if in a given brain the neuroglia stains well, this is always a proof of early preservation and fixation of the brain. In the first case in which the method of preliminary formalin injection was made one hour after death, and in which the autopsy was performed forty-three hours after death, pieces from four different regions, namely, cerebral cortex, cerebellar cortex, medulla oblongata and caudate nucleus, were removed twenty-four hours after the autopsy and subjected to the procedures required for the Mallory Phosphotungstic-hematoxylin neuroglia stain. The stain succeeded very well in all four regions, but of particular value was its success in the caudate nucleus which, as men-

tioned above, was softer than the other parts of the brain, *i.e.* not so well acted upon by the formalin. How well it succeeded is seen by the adjoining figure showing the neuroglia fibers and neuroglia nuclei of a part of the caudate nucleus. The penetrating value of the method is thus very aptly shown.

The great value of the method needs hardly to be emphasized. Every neuro-pathologist knows how important it is to fix and harden the central nervous system no later than six hours at the most after death. Here, we have means of preserving it immediately after death without inflicting any mutilation on the body and without changing the appearance of the intra-thoracic and

Figure showing a portion of the caudate nucleus stained with Mallory's phosphotungstic-hematoxylin neuroglia stain. Taken with Leits' ocular 4 and immersion 1-12 in.

intra-abdominal organs (with the exceptions mentioned) through the formalin.

The method has this advantage over the otherwise excellent method of formalin injection into the aorta as practised by Drs. Meyer and Dunlap, and elaborated in such an ingenuous manner by these gentlemen—it can be applied immediately after death in cases in which we are doubtful whether an autopsy will be permitted or not.

It has the further advantage over that method, of hardening not only the brain, but also the spinal cord; and the result is not inferior to that of their method.

An additional advantage is the small quantity of formalin required, one quart at the most being needed as against the 1½ to 3 gallons necessitated in Meyer's and Dunlap's method; and this advantage is not to be undervalued in view of the relatively high price of this drug.

OCCIPITOPOSTERIOR POSITIONS.*

By S. MARX, M.D.,
NEW YORK.

When I was requested to open the discussion on "Occipitoposterior positions," I thought that the last word had been said on this subject—that is, so far as the reader is concerned. The question of the management of occipitoposterior presentations has resolved itself into one of relative simplicity, not that any particular schematic therapeusis will be offered; for schemes in obstetrics, as well as in other specialties of medicines, often go wrong, but the experience offered by meeting many of these cases has allowed me to present fixed, though hardly dogmatic, views on the subject before us, for it is the belief that a finality has been reached with this question, as well as with many other obstetric questions. To be forewarned as to this complication is to be forearmed. It is far more frequently met than is usually thought and taught. But it occurs most frequently as a primary condition and at so early a stage is certainly not recognized or is not sought for; for it does not enter the mind of the attendant that it is possible to have a malposition of a normal presentation. Of my own personal statistics, I quote from my case book that in the last one hundred consultations in midwifery I have come in contact with twenty-three cases of persistent occipitoposterior positions. This, of course, does not carry with it much importance as to the absolute frequency of this complication, for as a consultant it is most natural to see nothing but complications. But of more importance is the careful review of the cases under my personal care, *i.e.* private cases—those examined from the onset of labor and in which there has been an early determination of the position, before the head has been markedly influenced. Here I have noted, in one hundred cases, seventy primarily posterior occiputs, certainly a larger percentage than I had any idea of; and we doubt not that if all practitioners took the necessary care for a careful and early examination the same high percentage would be found. For this reason I wish to record the fact that primary malpositions of the occiput are present in a much larger number of cases than we are led to believe. How much higher still the percentage may be before the advent of labor is impossible to tell, except by abdominal palpation, but for reasons elsewhere given I pin my faith on internal examination, relegating abdominal palpation to the position to which it belongs—namely, one of absolute unsafety.

And this leads up to the question of diagnosis. Even without an internal examination, the symptoms presented are so characteristic that a presumptive diagnosis can very often be readily made, and this triad of symptoms ought always be associated with a possible vicious presentation of the occiput, *i.e.* early rupture of the membranes, slow nagging and teasing pains and abnormal slow and futile labors. Such evidence can always be clinched by a vaginal examination, or, if the least doubt exists, the introduction of the full hand into the canal. It is absolutely essential for successful treatment to make an early and a clear diagnosis not only of position, but of presentation; and in this I am sorry to say too little is done, for the average practitioner always rests satisfied so long as the hard head presents, caring little or bothering less what area of the fetal head present. Early recognition and timely interference is more than half the battle won, for by such means we can, in an overwhelming majority of cases, change the case from an almost impossible one to one of the greatest simplicity, and thus carry it to a successful issue. But of the greatest import is still: What are you going to do in order to cope successfully with these cases? It must be remembered that a firmly flexed head will almost always rotate spontaneously, and that the first step in the treatment of these cases is to insure a permanent and marked flexion; and this can be most readily done by pressing, throughout several pains, the sinciput against the chest of the child by two fingers, or the introduction of the full hand in its grasp, flexing the occiput and thus obtaining the same result. The permanency of this sustained flexion is assured by using the postural treatment, *i.e.* placing the patient in that lateral prone position corresponding to the position of the occiput. These minor manipulations done early and carefully, as above described, will, in the great majority of cases, cause the head to rotate with resultant normal and spontaneous expulsion. It is advisable to undertake operative measures at a late period; or, to be more concise, operate only when there are

*Discussion opened before the Obstetric Section, New York Academy of Medicine, April 28, 1904.

present, symptoms to indicate that interference is warranted, symptoms the interpretation of which mean exhaustion on the part of the mother or child. In obstetrics early and uncalled interference is unwarranted and may lead to disastrous ends, while working in armed expectancy is often followed by remarkable and favorable results for mother and child, if only for the reason that in this complication, rotation occurs in a large majority late, *i.e.* when the head is low down on the pelvic floor. The secret of success lies in two directions: (1) operate only in the face of clear indications on the part of either mother or child; (2) operate at once when there is tendency to posterior rotation.

When either of the just mentioned conditions arise how are we to meet them?

Cæsarean section and symphyseotomy are included for the reason that we presuppose that we are dealing with a pelvis that is normal, and consequently these operations are beyond the scope of this paper. Yet it occasionally may happen that either one of the just quoted operations might have to be considered, especially the pubic section, in those rare cases in which the occiput is absolutely impacted and no other means can possibly give us a living child.

In quite a few of these cases, the perforator ought always be the instrument of selection, for it would be the height of folly and directly against the interests of the mother to attempt to deliver by another means than by a craniotomy upon a child whose life has already been sacrificed or at best whose vitality is so low that any form of operative measure would deliver a dying or hopelessly maimed child. A rule which I strictly adhere to, so far as circumstances allow, is to elect the perforator in all those conditions just mentioned, only in the presence of a child of good vitality I should elect either forceps or version, and my selection of these methods is practically sharply defined, *i.e.* version when the head is above the brim, forceps when the head is fixed at or below this point. What I wish to elucidate in this paper is the absolute value of the modern axis traction forceps. But I would preface my remarks by a note of warning. The modern axis traction is a dangerous instrument for the inexpert, even as it is absolutely safe in the hands of one accustomed to its use. It is a forceps for the expert only; and if by its use bad results accrue it is not the fault of the forceps, but of the operator. Its method of application and its action have been more fully gone into in another paper and cannot be entered into more fully here. But one important method of delivery will be discussed at length, and that is the method which has given almost uniform success and satisfaction. I have given it the name of "rotary axis traction," for by this manœuvre we fulfil a compound indication, *i.e.* axis traction and, at the same time, artificial rotation. These, as you will readily see, are particularly applicable to cases of posterior position of either the vertex or the face. I cannot improve upon my statements made in a former article and shall take the liberty of quoting the following from the same: In many of these cases of occipitoposterior positions I have succeeded, by the use of the Tarnier instrument, in rotating the head anteriorly by simply allowing it, while traction is being made, to be influenced by the factors supplied by nature (the resistance offered by the perineal structures and furthered by the turning points afforded by the ischial spines, especially when they are prominent) to provoke such rotation. And herein lies the utility of the instrument. It allows the head to pass uninfluenced through the pelvic canal, except for the natural influences which promote rotation; hence the great advantage is the free mobility of the forceps when applied to the head. This rotation begins to occur when the head descends to the pelvic floor, and is instantly evinced by the behavior of the blades—they begin to rotate with the head, the movement increasing with every traction effort, until the forceps has entirely rotated. When, however, such tendency to rotation does not occur, the normal mechanism is probably at fault, and it is then that "rotary axis traction" becomes of supreme value. The forceps may be applied according to the pelvic walls; but an oblique application, *i.e.* to the sides of the child's head, is better. When in such position, it conforms to one of the oblique diameters of the pelvis, insures a more certain grasp, and very materially aids in the success of this otherwise rather simple manœuvre. With the right hand, steady traction is made, and at the same time, with the left hand, the handles of the forceps are compelled, or at least influenced, by gentle rotation to turn in the direction of the presenting part; to the left in left occipitoposterior cases, to the right in right posterior ones. This manipulation must be persisted in, slowly rotating all the time while making careful and intermittent traction, timing our measure so that when the head reaches the pelvic outlet, complete rotation shall have occurred and the forceps blade shall be found nearly or entirely inverted. At no time should brute force be used, but the greatest gentleness exercised at all times. I have on a number of occasions tried forcible rotation by the ordinary forceps, and have succeeded, but often at the expense of the maternal structures, with resulting deep tears of the vagina and pelvic floors. "Rotary axis traction" has been tried innumerable times, and it has *seldom* failed when the forceps was applied to the sides of the pelvis, and *never** when it was applied to the sides of the fetal skull. The resultant lesions were no deeper or more frequent than in ordinary simple forceps extractions. The prognosis for the child was as good as under ordinary conditions.

*Since writing this article, however, I failed in one case to rotate even though the blades were applied to the sides of the fetal skull.

BRIEF NOTES ON THE MANAGEMENT OF OCCIPITOPOSTERIOR POSITIONS OF THE VERTEX.

BY JOHN O. POLAK, M.S., M.D.,
BROOKLYN, N. Y.
PROFESSOR OF OBSTETRICS, N. Y. POST-GRADUATE MEDICAL SCHOOL.

THE occurrence of a posterior position of the vertex is always indicative of faulty mechanism, it matters not whether the fault be a pelvic contraction of the flattened, general, oblique, or kyphotic form, a large head, a small child or a defective pelvic floor, imperfect flexion of greater or lesser degree, always occurs at some stage of the mechanism. Consequently when this malposition does present, it suggests some defection in the factors of labor and a recognition of the cause in the particular case must be appreciated before any treatment can be instituted.

Diagnosis.—Before labor and during the early part of the first stage, the diagnosis of occipitoposterior may be readily made by abdominal palpation. The dorsal plane is inaccessible, while the small parts are prominent and found in the middle section of the abdomen. The head is usually not engaged at the beginning of labor, which makes the cephalic prominence marked. The anterior shoulder is found remote from the median line and the heart is heard well around toward the flank or not heard at all. Right occipitoposterior must always be thought of in right dorsal positions, as it occurs nearly or quite as frequently as a right anterior position. A left posterior is less frequent than a right. The

vaginal signs are confirmatory. If the head is engaged, the small or posterior fontanelle may be felt opposite one or the other sacroiliac synchrondrosis with the ball of the occiput posterior. Usually, however, the head is not engaged at the beginning of labor, and further it is frequently improperly flexed, because of the conditions which obtain, in the causation of posterior occiputs. Hence the large fontanelle is at a lower level and is more easily felt. Palpation of the ball of the occiput and the relative location of the ears will make the diagnosis positive. It must be kept in mind that the most frequent cause of fetal dystocia is a posterior position of the vortex and when such is encountered, should there be any doubt in the mind of the operator as to the relations of the head to the pelvis an examination under anæsthesia with the hand in the vagina and two fingers or half the hand introduced into the uterus will remove all uncertainty. The relation that the sagittal suture bears to the diameters of the pelvis is a constant index as to the degree of rotation and must be observed to manage intelligently this abnormality.

Treatment.—The majority of posterior cases rotate to the front unaided when the passenger, powers and passages are normal or can be made to assume relative normality. Less than 2 per cent. rotate into the sacrum, notwithstanding that the head must rotate through 135° to be delivered with the occiput under the pubes. This rotation takes place either at the brim, in the cavity of the pelvis or on the pelvic floor.

When the diagnosis is accurately made in the beginning of labor, posterior positions are not as formidable as generally believed. The dangers to the mother are exhaustion, lacerations, and the risks of *instrumental interference*. To the child—those of a prolonged labor. In considering the management of this abnormality, it is advisable to study the individual case as it presents at the time when it is seen by the accoucher.

Therefore I would classify these conditions as follows:

1. With the head at or above the brim, flexion more or less imperfect, and the membranes unruptured. In the presence of these conditions, postural methods alone deserve our consideration. The woman should be placed on the side toward which the occiput points and directed to maintain this position, which favors anterior rotation and more perfect flexion of the vertex. The genupectoral position which is mentioned in most of our textbooks cannot be maintained by the patient for any length of time and so is only of theoretical value. Every effort should be made to keep the membranes intact until complete dilatation of the cervix is obtained. When dilatation is slow a colpeurynter will facilitate canalization and preserve the membranes.

2. After rupture of the membranes with the head at the superior strait, postural methods may be continued while efforts are being made to dilate the cervix with hydrostatic bags, unless the condition of mother or child demand more radical intervention.

After dilatation, a fair trial having been given to posture and the natural forces having failed to rotate the head to the front, manual rotation of the head to the front and engagement of the head by internal and external manipulation, under anæsthesia, may be attempted. This procedure presupposes a dilated or dilatable cervix. The one hand placed on the mother's abdomen pushes the anterior shoulder toward the median line, while the other hand in the uterus pushes the other shoulder in the opposite direction, thus rotating the dorsum anteriorly, as well as the head, and the tendency to recurrence is minimized. When the malposition of the occiput has been corrected, an attempt to engage the properly flexed and positioned head may be made with the patient in the Walcher position, either by crowding the head into the pelvis manually or by tentative traction with the axis traction forceps. Should this attempt to engage the head fail, podalic version may be elected, except when the size of the child would contraindicate such a procedure. The writer feels that while version is theoretically the proper thing to do in these posterior cases, which have resisted the several efforts of the operator to flex and engage the vertex, experience in estimating the relative size of the child and the pelvis as well as the individual dexterity of the operator will largely determine whether an axis traction delivery or a podalic version shall be elected.

When the head presents as an occipitoposterior in the cavity, anterior rotation may be favored by posture, used in conjunction with manual aid during the pain, by pushing the sinciput upward and backward, thus promoting flexion and anterior rotation. Should the head become arrested and remain stationary for two hours in the second stage, the forceps may be applied, either to the sides of the pelvis and taken off and reapplied as the head assumes its relation to the different pelvic planes or the axis traction forceps may be applied to the sides of the head and be used as rotators as well as tractors, guided by the relation of the saggital suture.

When a posterior vertex is encountered on the pelvic floor, the occiput may be rotated to the front manually or with the reversed forceps, though this possibility only obtains in the case of a small fœtus on a relatively roomy pelvis. Should attempts at rotation of the occiput fail and a posterior position persist, the brow may be pushed upward to exaggerate the flexion while the occiput is slipped over the perineum with more or less tearing of the pelvic floor.

Posterior positions are apt to tire the woman and exhaust the child. The fœtus often becomes asphyxiated while in the vagina. The judicious use of forceps will minimize these risks.

In conclusion I would add, make the diagnosis and then apply such treatment as the individual case demands, being governed by the existing conditions at the time at which the patient is seen by the attendant.

287 Clinton Avenue.

Exanthematous Eruptions Following Throat Operations.—From his personal experience and from a careful study of the literature of the subject, Louis Fischer believes that exanthematous eruptions, such as scarlet fever or measles, have nothing to do with the operation itself. The infection evidently takes place before the operation. The period of incubation may have been shortened, and that the disease appear sooner owing to the traumatism. The question of prophylaxis by means of local pharyngeal antisepsis to destroy pathogenic bacteria in these regions is one that deserves attention. It is important to ascertain, if possible, whether or no the patient has been exposed to any infectious disease for a number of days prior to the operation. The thermometer is of valuable assistance. If the temperature is above normal it is better to postpone operative procedure until normal conditions are established. Fischer believes the infection takes place before the operation, and that the operation itself lowers the resistance of the body, and shortens the period of incubation. This will account for all of his cases and those reported by many clinical observers, being called surgical scarlet fever, when in reality they are true cases of scarlet fever, infected prior to the operation.—*The Laryngoscope.*

AUTOINTOXICATION OF INTESTINAL ORIGIN.

THE question of antointoxication is treated quite extensively by Dr. G. Lyon in the *Gazette des Hôpitaux* for May 14 last. The intestine is a permanent source of poisons, which under certain conditions cause grave alterations in the principal organs (notably the liver, kidneys, and skin) and functional troubles, among which those of the nervous system occupy a prominent place. Autointoxication may exist in connection with diseases involving diarrhœa, but it is above all associated with those causing constipation; it is, in short, a consequence of all intestinal affections.

To understand its genesis, we must at the outset recognize that digestion is a double process, an enzymic and a microbic one. Both enzymes and microbes transform starch into sugar, both emulsify fats, and both transform albuminoids into peptone. But the rôle of the microorganisms does not end here, for they may act to bring about further and putrefactive changes, with the formation of sulphuretted hydrogen, lactic and butyric acids, and from the albumins the ptomains and substances of the aromatic group. Against the poisons so produced, the normal organism manages to protect itself principally through the action of the intestinal epithelium and the liver which destroy the majority of the toxic products, while the excretory organs eliminate the remainder. Given certain conditions, however, and the toxic products can be generated in excess of the powers of the organism to dispose of them, or those powers may fail in point of efficiency. Of these two conditions, the former is the more frequent. Various influences may interfere with the normal course of digestion. Errors in diet, qualitative or quantitative, may form the starting-point, or the cause may lie in the organism itself. Thus gastric atony, whether combined (as is frequently the case) with dilatation or not, plays an important rôle. Or any one of several modifications of the gastric juice may initiate the series, by entailing delayed digestion which means fermentations and putrefactions. But gastric conditions are as nothing compared to intestinal, as gastric defects can be made up by intestinal over-exertion, while for intestinal deficiencies there is no compensation. Apart from organic obstructive conditions, intestinal atony plays a frequent and very deleterious part, the more serious the higher in the intestine the stasis occurs. For once stasis sets in, we are already in sight of autointoxication. Another expression of this motor insufficiency is the constipation so often present. As other pathological conditions underlying autointoxication are enteritis (acute or chronic), colitis with constipation, cancer of the intestines, etc., but especially chronic appendicitis, as its rôle is in a number of cases misconceived. The fetid diarrhœa, which is very frequent in the last disease, and which is very rebellious to treatment, ceases at once upon ablation of the appendix. Autointoxication may then be associated with any disease of the intestines, those associated with diarrhœa as well as those connected with constipation, but it is far more frequently associated with the latter class.

The diagnosis of chronic autointoxication is easily made; the yellowish tint of the face with the coated tongue, fetid breath, anorexia, nausea and sometimes vomiting, constipation, or diarrhœa with fetid stools, usually emaciation, sad aspect, with loss of energy and inaptitude for work, the whole gamut of nervous troubles (migraine, torpor, vertigo, insomnia, multiple pains), make up the picture.

As regards the degree of intoxication taking place, the severity of the clinical symptoms affords no accurate indication, and the same is true of the examination of the stools. Some patients have numerous very offensive stools with few symptoms, while others with a few apparently normal stools show a profound intoxication. It is then important to recognize that we have in the condition of the urine (in which the majority of the toxic products is excreted), a quite accurate index to the state of affairs. Besides the bodies produced by both enzyme and microbic action, the microorganisms of the intestinal tract are capable of giving rise to putrefactive products; bodies belonging to the fatty series (ammonium butyrate, caproate, valerianate; ptomains), and to the aromatic series (phenol, paracresol, indol, scatol, aromatic oxyacids). These appear in the urine as sulphocompounds, their toxicity having been attenuated by combination in the liver with sulphuric and glycuronic acids. The aromatics have not the toxicity of the ptomains but they are excreted parallel with them, and constitute, therefore, a rather exact index to the amount of the ptomains. A number of observations have now shown that putrefaction of the food in the prima viæ is the *only* source of the "ethereal sulphates" in the urine, and that they are never derived from any of the albuminoids of the organism itself. Thus, in animals with sterilized intestines, fed with sterile food, the urine shows no trace of phenol, indol, or scatol. More important, from the practical standpoint, is the fact determined by White, Poehl, Herschler, Winternitz, and Bernacki, that limitation to a hydrocarbonaceous diet, brings about a reduction of these substances in the urine to one-third of the previous amount. On the other hand constipation increases the amount of the ethereal sulphates in the urine, as does also all obstructive conditions of the intestines. The latter fact would naturally lead one to suppose that purgatives would bring about a decrease. But the action of these drugs is, in fact, not a uniform one, castor oil and the salines increasing the amount of the urinary ethereal sulphates, while calomel decreases them markedly.

As regards successful treatment, the first indication is the retardation of the existing intestinal putrefaction. For this purpose sterilization of the intestine by means of drugs has been tried, but the practice is to-day discredited as an impracticable utopia. The effects of naphthol and its derivatives are, it must be said, much disputed and most disputable. Besides naphthol exercises an irritation of the most active description on the stomach, and its prolonged use can cause glandular atrophy. Also the administration of hydrochloric acid is useless, at any rate as regards intestinal antisepsis, and it may be remarked that hyperchlorhydria does not include antisepsis in its symptomatology. The same is, however, not true of lactic acid, which diminishes markedly the urinary ethereal sulphates.

It is, however, by diet that *the* effect is to be produced. To start with, the albuminoids are to be reduced to a minimum, for it is their fermentation which yields the toxins. Combe recommends "saturation" of the patient with hydrocarbonaceous articles of diet, the word "saturation" being taken in its most literal acceptation. This antiputrefactive diet of Combe yields the most excellent results. Also Pochl and Bernacki have proven that a milk diet diminishes the ethereal sulphates, and that on such a diet the stools contain no indol, scatol, or phenol, but only leucin and tyrosin. This resistance of milk to putrefaction is attributed by Winternitz to the contained lactose, which on fermentation produces lactic acid which in its turn inhibits putrefaction. Similarly, fresh cheese has been shown to possess antiputrefactive properties. As regards eating, meals should be alternately solid and liquid, the patient not eating when he is drinking, or *vice versa*. Rovighi and Schumann have shown that this course involves a diminution of the ethereal sulphates. After each solid meal the patient should lie down, without sleeping. Green vegetables and all fruits, cooked or raw, are to be excluded. After a variable time the milk-farinaceous diet is to be mitigated on trial with meat, the yolk of eggs, and green vegetables.

Enteroclysis has more value than as an enema. The water is absorbed, relieving thirst and assisting in the lavage of the blood. The tube should be introduced with the patient lying on the right side with the left leg flexed upon the abdomen, and very slowly with successive pauses, to allow of an unfolding of the rugæ in advance of it. The solution is best an isotonic one (7 parts of sodium chloride per 1,000) introduced at 38°, and under a low pressure (with an elevation of only 15 to 20 centimeters), to avoid spasm of the intestine. Purgatives and lavage should be alternated. The purgative of election would seem to be calomel.

In certain cases with profound intoxication (as evidenced by nervous troubles, oliguria, subicterus, etc.) in which an immediate effect is urgently demanded, subcutaneous injections of saline solutions are to be resorted to, as this is the only method which can be relied upon for a rapid deintoxication of the organism.

The immediate symptoms being relieved, in the further treatment recourse should be had to hydrotherapy, open-air life, exercise, subcutaneous injections of sodium cacodylate and of strychnine; and gastrointestinal massage is one of the best means at our disposal for the correction of the stasis.

PARATYPHOID FEVER.

In the *Scottish Medical and Surgical Journal* for May is a paper by Dr. R. D. Keith on paratyphoid fever. The first part of the article is devoted to a consideration of the disease chronologically, and states that the first case was described by Achard and Bensaude of Paris in 1896, who isolated a paratyphoid bacillus. Schottmüller of Hamburg was the first observer to take up the subject in Germany, who isolated the specific organism of the disease and gave to the fever the name paratyphoid on account of its close resemblance to typhoid fever. Schottmüller concluded, from the investigation of a large number of cases of clinical typhoid in the General Hospital of St. George in Hamburg, that the bacilli isolated were the cause of the disease, and that of six cases there were two groups, one of which contained two, and the other four bacilli. These two groups, subsequently described in the literature as type "A" and type "B," differ in degree both culturally and in their serum reactions. It was found that the serum reactions of the members of the first group corresponded with one another, but not with those of the second group, and that while the serum reactions of the members of the second group corresponded with one another they differed from those of the first. These conclusions in all important details have been confirmed by the investigations of many observers, including several Americans.

As to the clinical characteristics of paratyphoid fever, observations of more than one hundred cases have been published, of which, however, only 46 are available for the purpose of a minute clinical analysis. Dr. Keith describes the disease—although, as he confesses, somewhat loosely—as an acute infectious process caused by a bacillus closely resembling in many particulars the typhoid bacillus, and the symptoms and course of the disease closely resembling those of typhoid fever. The onset is marked by headache, lassitude, loss of energy, and general weakness. Occasionally there is epistaxis, and in some cases vomiting and pain in the abdomen. By the time the patient comes under observation he is feverish and may feel chilly, but regularly marked rigors are hardly ever met with. As a rule, the temperature does not rise above a moderate height (102° F. or thereby), except in the more severe cases, nor does it remain for more than a few days at this height continuously.

Occasionally a critical fall is observed, and it has been observed by most investigators that even at its height the temperature has, as a rule, a remittent or intermittent character. The pulse is, as a rule, quite regular but somewhat small. Its frequency, according to some, is not increased at the commencement of fever.

A roseolar eruption resembling that of typhoid fever was present in thirty-two out of forty-six cases. It was described in some cases as occurring not only on the skin of the abdomen and chest but also on the back and limbs, and in one case even on the face. The tongue is generally covered with a moist white coating, but is occasionally dried and furred.

Diarrhœa is more prominent than constipation, and is sometimes present at the commencement of the disease. The abdomen is not, as a rule, markedly distended, nor is tenderness a prominent feature, but pain is in some cases present, and iliac gargling is an almost invariable accompaniment of the disease. The spleen is enlarged in the majority of cases, but so far as can be ascertained during life the liver is not affected. The urine during the course of the disease shows a deposit of lithates. Albuminuria, when present, is, as a rule, not marked and is found during the height of the fever. Hyaline and granular casts have been observed, and in one case blood was found to be present. In nineteen out of forty-six cases the urine was found to give the diazo reaction, and in eight the test for indican was positive. The heart is practically always unaffected. With regard to the lungs, bronchitis is comparatively common, and emaciation is not so marked in this disease as in typhoid fever.

Of the complications observed, bronchitis is the most common. Pharyngitis is not uncommon, and next in frequency to it comes bronchopneumonia. Thrombosis of the femoral veins, pleurisy, phlebitis of the veins of the leg, endocarditis and cystitis have also been observed. Sequelæ have not definitely been known to occur.

Up to the present only three authentic fatal cases have been described. In all of these paratyphoid bacilli have been isolated from the organs after death, but in no case was any characteristic lesion found. The appearances were in most cases those of an acute general infection.

Studies undertaken to show the morphology, cultural characteristics, and behavior toward various media of the bacillus of paratyphoid fever bring out the characteristics distinctive of the paratyphoid bacilli "A" and "B." It is shown: (1) That there is a distinction between "A" and "B" paratyphoid bacilli. (2) That as regards the characteristics here alluded to paratyphoid "A" organisms are on the whole nearer bacillus coli than the "B" group. (3) That bacillus paratyphoid "B" is identical as regards its cultural characteristics with Gärtner's bacillus. (4) That "A" and "B" paratyphoid bacilli are distinct both from the bacillus coli communis and the bacillus typhosus.

Dr. Keith considers the serum reactions in cases of paratyphoid infections and their bearing on the serum test in typhoid fever. The chapter in which this portion of the subject is dealt with is both too long and too technical to be adequately treated in an editorial. The value of immune sera is pointed out (1) As a means of identifying bacilli quickly. (2) As a means of showing the more exact relationship of bacilli to other members of a family or group.

The author gives the following résumé of the conclusions drawn from the investigations considered by him: (1) That there exists a disease which simulates the disease known as typhoid fever so closely that they can only be distinguished by bacteriological means. (2) That the disease is caused by an organism which exists in two varieties and which may be regarded as bacteriologically intermediate between the bacillus typhosus and the bacillus coli communis. (3) That the disease is on the whole mild and that the prognosis is good. (4) That the treatment of the disease is similar to that of typhoid fever. (5) That the disease spreads in the same manner as typhoid fever, and that the same hygenic and general measures should be taken in cases of this disease as are adopted in typhoid fever. (6) That in suspected typhoid-like cases a bacteriological examination is of the greatest importance both for diagnosis and prognosis and should be made wherever it is possible. (7) That up to the present the disease must be regarded as acute general infection in which no definite local lesion has been shown to exist.

Paratyphoid fever is probably conveyed in the same manner as is typhoid fever. It is not markedly infectious. The incubation period is about fourteen days, the spots appearing from the twentieth to twenty-sixth day. Perhaps the most valuable deductions to be drawn from the investigations of paratyphoid fever is that experiments have tended to show that immune sera can be produced which have a protective power against lethal doses, not only of homologous organisms but also of organisms which are related, thereby indicating to some extent the possibility of a new line of treatment in cases of infectious diseases.

Wright, as is well known, is of the opinion that typhoid fever can be warded off completely in some cases and in others rendered less severe by injections of dead cultures. Dr. Keith suggests that the indications given by the results of the experiments on animals with protective sera in the case of bacillus typhosus and allied organisms is but the initial stage of a new curative method of treatment. This matter, however, requires further elucidation before any large definite statements can be made regarding it. Nevertheless, it may be said that the prospect is hopeful.

Trachoma as an Epidemic and Maritime Disease.

In the annual report of the Surgeon-General of the Public Health and Marine Hospital Service for the fiscal year 1903, recently issued, Passed Assistant Surgeon J. M. Eager has an article on the above subject. The writer points out that the transmissibility and relation to shipping of trachoma are brought prominently before the observer in connection with the inspection of emigrant ships in Italy. In view of the contagiousness of trachoma, the Italian Government now refuses to allow the embarkment of cases of active ophthalmia on emigrant ships leaving Italy, either for South America, where there is no prohibition against the entrance of trachoma, or for the United States. The object of this ruling is to prevent the spread of the disease aboard ship.

Dr. Eager reviews the history of trachoma from an epidemiological standpoint, and says that while it may be considered as a disease which, though known in ancient times to be contagious, was not noted to take on an epidemic character until recent centuries. Hippocrates, Galen, Plutarch of Cheronea, and Rhases, the famous Arabian physician of the ninth century, mention ophthalmia as an eminently contagious malady. The Rabbi Moses, a great exponent of the doctrines of Galen, says in his aphorisms that to gaze steadily into the eyes of a trachomatous person is enough to make anyone's eyes water, and that continuous contact with sufferers from ophthalmia generally results in contracting the disease.

The name trachoma was given to the affection

through the writings of Prospero Alpino, an Italian, who visited Africa in the sixteenth century for the purpose of studying Egyptian medicine. It was through the campaigns of Napoleon that trachoma became prevalent throughout Europe. All the armies engaged in those wars being more or less affected by the disease. In 1820 Guillé of Paris demonstrated the contagiousness of trachoma.

The only record found in literature of trachoma as a maritime disease is that given by Guillé (Bibliothèque ophthalmologique, Paris, 1820). The disease occurred on a slaveship, *Le Rodeur*, which on the voyage out was free from ophthalmia, but whose slaves when sixteen days from Guadeloupe exhibited signs of the malady, which soon spread in the most rapid manner.

At the present time trachoma is notably endemic in Arabia, Egypt, Italy, Spain, Western Russia, Poland, Ireland, and South America. Exact statistics as to the prevalence of trachoma in Italy are not available, but these are, in most instances, incomplete, and in others, owing to inherent disadvantages, entirely indecisive. However, enough is known to show that the disease is very prevalent in many ports of Italy. Dispensary reports establish the fact that trachoma is greatly on the increase in that country, while Professor Fortunato states that in some of the maritime places of Sicily and Sardinia, from all available means of observation, it may almost be said that the entire population is trachomatous.

Dr. Eager ends an instructive paper by saying that the statistics of the medical inspection made in Italy for the United States are of little value in estimating the prevalence of trachoma in Italy for the reason that the figures are distorted by the fact that often persons notably trachomatous do not attempt to take passage or are refused the same by the transportation companies prior to the day of sailing, and so do not appear at the regular medical visit. . . . Then, too, many persons, some not trachomatous, but fearing they may fall under suspicion, and others really victims of the disease, practise a sort of universe malingery at the time of the inspection. Adrenalin with cocaine hydrochlorate is a favorite prescription for eyedrops. By its application, a blanching of the conjunctiva is brought about, a condition which, even in the absence of other evidence, is sufficient to put the person under observation until the disappearance of drug effects has rendered proper examination practicable.

Food Preservatives.

A committee has recently been sitting, taking evidence as to adulterations and the use of preservatives in food. It has been especially considering the question of the use of preservatives in food. According to the *New York Times*, Dr. Frear, in discussing this contention, said that the testimony of the manufacturers had pretty generally been that such goods could not be packed without preservatives without a certain percentage of loss, but we must remember that the housewife who puts up her own catsup and preserves also suffers a percentage of loss. "The best opinion," Dr. Frear says, "seems to be against the use of preservatives as a general proposition as injurious, but, on the other hand, it is argued that the quantity used is so small as to be harmless in the products in which they are most necessary. The manufacturers seem to believe that it ought to be enough if all goods containing preservatives were plainly labeled, so that the consumer could see for himself, and take the responsibility for what he is taking into his stomach."

It is expected that the Secretary of Agriculture will be able in a few months to draw up a set of standards which will define what is meant by purity in foods, and what constitute adulterations. The Medical Record has always taken the view that preservatives should, as far as is possible be absent from foodstuffs. In fact, there is little doubt that in the large majority of cases articles of food require no preservatives. By allowing the use of foreign matter in food, the thin edge of the wedge for all kinds of deception is allowed to enter. Undoubtedly, if the use of preservatives is permitted at all, food so treated should be plainly labeled. The question of pure food is a momentous matter, and one which directly affects the whole community. Ignorant persons must be protected against themselves, and the manufacturers must remember that it is not only their interests which are at stake but the welfare, to a greater or lesser extent, of the entire population of the country. Selfish interests cannot be allowed to prevail over the good of the many, and legislation should be strictly enforced which clearly defines the relative position of manufacturers and the general public with regard to food preservatives.

The Medical Library Movement in the United States.

Standard books on medicine and surgery, and the latest works on these subjects, together with the most recent medical literature, are considered to be essential to the physician of the present day. Without access to these the up-to-date medical man feels to some extent lost, for he recognizes that it is necessary for him to keep abreast with the times and to know something of everything that is going on in the medical world everywhere. Thus the medical library has become an absolute need, and the main provider of medical and scientific pabulum to the practitioner. As a factor in medical education the library is of inestimable value, in this respect equalling if not transcending any other means.

Dr. Albert T. Huntington of Brooklyn, in the *Medical Library and Historical Journal*, for April, 1904, writes on the medical library movement in the United States. The first one in this country was founded in 1760, but it is only within the past forty years that the great medical libraries of to-day have been built up, and only within the last decade that the medical library movement has become active and widespread.

Dr. Huntington gives a list of the various medical libraries in the country, the date of their foundations, and the number of volumes contained in each. There are in the United States 215 of such institutions, while the number of volumes in these is estimated at 1,023,295.

The author points out that if we should assume that all the libraries in the list compiled by him are in an active state of existence and their resources readily available to the profession, two striking facts are very evident: First, that certain centers are oversupplied with medical libraries, and that the fusing of several distinct collections into one great library whose resources should be free to the whole profession could not be other than advantageous to the best interests of all concerned. Second, that there are certain large sections of the country which are utterly barren of adequate medical library resources.

Dr. Huntington is of the opinion that there are two requisites for the establishment and permanent success of a medical library: First, a desire on the part of the local profession to have a library;

second, the control of that library, wherever the books are housed, by the medical profession. Therefore, it is best, whenever practicable, that the library should be separate, and under the auspices of some general medical organization. The foregoing is undoubtedly good advice and should be followed as far as is possible.

The medical library movement has evidently taken firm root in the United States, and from all appearances will flourish in the future to a greater extent than at present.

News of the Week.

Change in the Examination for the Army Medical Service.—The examination of applicants for commission in the Medical Corps of the Army was materially modified on July 1. Immediate appointment of applicants after successful physical and professional examination—the latter embracing all subjects of a medical education—will be discontinued, and hereafter applicants will be subjected to a preliminary examination and a final or qualifying examination, with a course of instruction at the Army Medical School in Washington intervening. The preliminary examination will consist of a rigid inquiry into the physical qualifications of applicarts and written examination in mathematics (arithmetic, algebra, and plane geometry); geography; history (especially of the United States); Latin grammar, and reading of easy Latin prose; English grammar, orthography, composition; anatomy; physiology; chemistry and physics; materia medica and therapeutics; normal histology. The subjects in general education above mentioned are an essential part of the examination and cannot under any circumstances be waived. The preliminary examination will be conducted concurrently throughout the United States by boards of medical officers at most convenient points; the questions submitted to all applicants will be identical, thus assuring a thoroughly competitive feature, and all papers will be criticised and graded by an Army Medical Board in Washington. Applicants who attain a general average of 80 per cent. and upward in this examination will be employed as contract surgeons and ordered to the Army Medical School for instruction as candidates for admission to the Medical Corps of the Army; if, however, a greater number of applicants attain the required average than can be accommodated at the school the requisite number will be selected according to relative standing in the examination.

The course of instruction at the Army Medical School will consist of lectures and practical work in subjects peculiarly appropriate to the duties which a medical officer is called upon to perform. While at this school the students will be held under military discipline, and character, habits, and general deportment will be closely observed. The final or qualifying examination will be held at the close of the school term, and will comprise the subjects taught in the school, together with the following professional subjects not included in the preliminary examination: Surgery, practice of medicine; diseases of women and children; obstetrics; hygiene; bacteriology, and pathology; general aptitude will be marked from observation during the school term. A general average of 80 per cent. in this examination will be required as qualifying for appointment, and candidates attaining the highest percentages will be selected for commission to the extent of the existing vacancies in the Medical Department. Candidates who attain the requisite general average who fail to receive commissions will be given certificates of graduation at the school and will be preferred for appointment as medical officers of volunteers or for employment as contract surgeons; they will also be given opportunity to take the qualifying examination with the next succeeding class.

It is not thought that, for the present at least, the number successfully passing the preliminary examination will be greater than can be accommodated at the Army Medical School, nor that the number qualifying for appointment will exceed the number of vacancies. If, however, the class of candidates qualifying should be larger than is now thought, the young physicians who fail to receive commissions will not have wasted their time, as the course of instruction at the school, while in a large measure specialized to Army needs, is such as will better fit them for other professional pursuits, and furthermore they will have received a fair compensation while under instruction.

Admission to the preliminary examination can be had only upon invitation from the Surgeon-General of the Army, issued after formal application to the Secretary of War for permission to appear for examination. No applicant whose age exceeds thirty years will be permitted to take the examination; this limit of age will be rigidly adhered to. Hospital training and practical experience are essential requisites, and an applicant will be expected to present evidence of one year's hospital experience or its equivalent (two years) in practice. The first preliminary examination under the amended regulations above referred to will be held about August 1, 1904; those desiring to enter the same should at once communicate with the Surgeon-General of the Army, Washington D. C., who will furnish all possible information in regard thereto.

New York State Hospital for Incipient Tuberculosis.—This institution was opened on July 1, at Ray Brook, Essex County, under the superintendence of Dr. John H. Pryor. The following information concerning the admission and maintenance of patients is from the act establishing a State Hospital in the Adirondacks for the treatment of incipient pulmonary tuberculosis.

Free Patients.—The trustees of the hospital are hereby given power and authority to receive therein patients who have no ability to pay, but no person shall be admitted to the hospital who has not been a citizen of this State for at least one year preceding the date of application. Every person desiring free treatment in the hospital shall apply to the local authorities of his or her town, city, or county having charge of the relief of the poor, who shall thereupon issue a written request to the superintendent of said hospital for the admission and treatment of such person. This request must state in writing whether the person is able to pay for care and treatment while at the hospital. The requests will be filed by the superintendent in a book kept for that purpose in the order of their receipt by him. When the hospital is completed and ready for the treatment of patients, or whenever thereafter there are vacancies caused by death or removal, the superintendent shall issue a request to an examining physician, in the same city or county, or, if there is no such examining physician in the city or county, then the nearest examining physician, for the examination by him of said patient. Upon the request of the superintendent the examining physician shall examine all persons applying for free admission and treatment in the institution, and determine whether such are suffering from incipient pulmonary tuberculosis. No person shall be admitted as a patient in the institution without the certificate of one of

the examining physicians certifying that such applicant is suffering from incipient pulmonary tuberculosis. Admission to the hospital shall be made in the order in which the name of applicants shall appear upon the application book kept by the superintendent of the hospital, in so far as such applicants are subsequently certified by the examining physician to be suffering from incipient pulmonary tuberculosis. Every person who is unable to pay for care or treatment shall be transported to and from the hospital at the expense of the local authorities. At least once in each month the superintendent of the hospital shall furnish to the comptroller a list countersigned by the treasurer of the hospital of all the free patients in the hospital, together with sufficient facts to enable the comptroller to collect from the proper local official having charge of the relief of the poor such sums as may be owing to the State for the examination, care and treatment of the patients who have been received by the hospital and who are shown to be unable to pay for their care and treatment. The comptroller shall thereupon collect from the local official the sums due for the care and treatment of each such patient at a rate not exceeding five dollars per week for each patient.

Private Patients.—Applicants for admission to this institution who are able to pay for their care and treatment are not required to obtain a written request from the local authorities having charge of the relief of the poor, but should apply in person to the superintendent, who will enter the name of the applicant in the book to be kept by him for that purpose, and when there is room in the hospital for the admission of the applicant without interfering with the preference in the selection of patients, which shall always be given to the indigent, such patients shall be admitted to the hospital upon the certificate of one of the examining physicians, which certificate shall be kept on file by the superintendent. The trustees shall have power and authority to fix the charges to be paid by patients who are able to pay for their care and treatment in the hospital or who have relatives, bound by law to support them, who are able to pay therefor.

Examining Physicians.—In the Manual of the State Board of Charities for 1903, it is stated that the trustees of the New York State Hospital for the Treatment of Incipient Pulmonary Tuberculosis will appoint in all the cities of the State reputable physicians, citizens of the State of New York, to examine all persons applying for admission to the hospital. There are to be not less than two nor more than four of such examining physicians appointed in cities of the first-class, and two each in cities of the second and third class. The examining physicians must have been in the regular practice of their profession for at least five years, and must be skilled in the diagnosis and treatment of pulmonary diseases. Their fee for each patient examined will be three dollars. The law expressly provides that not more than one-half of all the physicians to be appointed under this section shall belong to the same school of medical practice. The examining physicians for New York City are Dr. H. M. Biggs and Dr. Egbert Le Fevre. Other examiners throughout the State are Dr. S. B. Ward of Albany, Dr. Elsner of Syracuse, and Dr. H. R. Hopkins of Buffalo.

Examinations of the Public Health and Marine Hospital Service.—A board of officers will be convened to meet in Washington, D. C., Monday, October 3, 1904, for the purpose of examining candidates for admission to the grade of assistant surgeon in the Public Health and Marine Hospital Service. Candidates must be between twenty-two and thirty years of age, graduates of a reputable medical college, and must furnish testimonials from responsible persons as to their professional and moral character. The usual order of the examination is (1) physical, (2) oral, (3) written, and (4) clinical. In addition to the physical examination, candidates are required to certify that they believe themselves free from any ailment which would disqualify them for service in any climate. The examinations are chiefly in writing, and begin with a short autobiography of the candidate. The remainder of the written exercise consists in examination on the various branches of medicine, surgery, and hygiene. The oral examination includes subjects of preliminary education, history, literature, and natural sciences. The clinical examination is conducted at a hospital and, when practicable, candidates are required to perform surgical operations on a cadaver. Successful candidates will be numbered according to their attainments on examination, and will be commissioned in the same order as vacancies occur. Upon appointment the young officers are, as a rule, first assigned to duty at one of the large hospitals, as at Boston, New York, New Orleans, Chicago, or San Francisco. After five years' service, assistant surgeons are entitled to examination for promotion to the grade of passed assistant surgeon. Promotion to the grade of surgeon is made according to seniority, and after due examination as vacancies occur in that grade. Assistant surgeons receive sixteen hundred dollars; passed assistant surgeons, two thousand dollars, and surgeons, twenty-five hundred dollars a year. When quarters are not provided, commutation at the rate of thirty, forty, and fifty dollars a month, according to grade, is allowed. All grades above that of assistant surgeon receive longevity pay, ten per centum in addition to the regular salary for every five years' service up to forty per centum after twenty years' service. The tenure of office is permanent. Officers traveling under orders are allowed actual expenses. Further information may be obtained by addressing the Surgeon-General, Public Health and Marine Hospital Service, Washington, D. C.

The Sanitary Degradation of Santiago.—On July 1 the municipal government of Santiago de Cuba discharged forty sweepers of the street cleaning force and fifteen cartmen, alleging that the step was made necessary by lack of funds. The remainder of the force refused to work until they had been paid their wages for May and June. It is stated that the streets have been in a filthy condition since the flood, and many families are moving to the country to escape the epidemic, which they fear may result from the neglect of all sanitary precautions. The local press bitterly criticises the Havana government for its failure to provide and carry out necessary sanitary measures, and is urging the foreign consuls to bring the situation to the notice of their governments.

Popular Tracts on the Prevention of Tuberculosis.—The Committee on Sanitation of the Central Federated Union and the Committee on the Prevention of Tuberculosis of the Charity Organization Society have published a pamphlet on the prevention and cure of pulmonary tuberculosis, which bears the title, "Don't Give Consumption to Others; Don't Let Others Give It to You." It describes a number of the sanitary safeguards, which tend to check the spread and progress of the disease. Copies of the pamphlet may be had in English,

Yiddish, Bohemian, and German upon application to the Charity Organization Society, 105 East Twenty-second Street.

Excess of Zeal on the Part of a State Medical Examiner.—The State Board of Medical Examiners of California secured, on June 18, the conviction of another physician for practising without a license, and the minimum fine of $100 was assessed. Following immediately upon this case, another action was brought for which the president of the board is being severely censured. A young physician, a graduate of the University of Basel, and recently a fellow at Johns Hopkins, arrived in the city shortly after the last regular session of the board. Recognizing that he could not engage lawfully in practice, he refrained from opening an office. In recognition of his capability, however, he was asked to serve as the assistant to one of the attending physicians of the city and county hospital. Even in this capacity, it is stated, he refrained from writing prescriptions. His conduct, nevertheless, met with the disapproval of the president of the board, who regarded it as a violation of the law, and summoned him to his office. Failing to arrive at a satisfactory understanding, he placed him in the custody of a police officer in waiting, and a trial followed on June 21 and 22. The police judge has withheld his decision, but stated that no fine will be imposed, in case of conviction, owing to the peculiar circumstances. From the fact that the cities of the Pacific coast are overrun by the worst of charlatans, who make of the tourists an easy prey, the action of the official who caused the arrest of a young man of ability who was only waiting for the opportunity to obtain legal recognition, has caused much comment.

An Illegal Practitioner Fined.—A man, styling himself a doctor of therapeutics, on the diploma of the Eastern College of Electrotherapeutics and Psychologic Medicine of Philadelphia, was recently convicted in Philadelphia of practising medicine illegally, and made to pay a fine of $200. This was the result of a suit instituted by the Pennsylvania State Board of Medical Examiners.

Health Department Changes.—Dr. Thomas Darlington, president of the Health Department, transferred all the assistant sanitary superintendents last week. He said it was "for the good of the service." Dr. Walter Bensall was sent from Manhattan to Brooklyn, Dr. P. J. Murray from Brooklyn to Queens, Dr. Gerald Sheil from the Bronx to Manhattan, Dr. J. T. Sprague from Richmond to The Bronx, and Dr. J. P. Moore from Queens to Richmond.

Dr. Emily Dunning, who was the first woman to be appointed an ambulance surgeon, has become, in the regular course of service, house surgeon of Gouverneur Hospital and began her duties on July 1.

Ambulance Accidents.—The third collision of a Bellevue Hospital ambulance with a Third Avenue electric car occurred a few days ago. The surgeon in each instance was seriously injured, and two of them are now in the hospital suffering from the results of their injuries. It would seem to be advisable for the drivers of ambulances to slow up when approaching car crossings, until they see that the coast is clear, even at the expense of losing a few seconds in responding to the call.

The New Vienna General Hospital.—On June 21, 1904, the Emperor of Austria laid the cornerstone of the new Allgemeines Krankenhaus, to take the place of the present famous building. The new hospital will in reality be a village of fifty buildings and will contain every device and appointment known to medical science. It is the aim of the directors of this gigantic hospital to make it the finest, best, and most completely equipped hospital in the world. It will be built upon one of the hills of Vienna, overlooking the present site, and the grounds will be much more beautiful than those of the present hospital.

Dr. Charles F. Roberts, Sanitary Superintendent of the Health Department of this city, on July 1 received a medal from his associates commemorating thirty-six years of service in the department. Dr. Darlington presented the medal in the rooms of the Health Department. In thanking his friends, Dr. Roberts recalled the fact that thirty-six years ago the population of New York was 800,000 and the death rate 36 a thousand, while to-day, with a population of 3,800,000, the death rate is 19 a thousand.

The Late Dr. Grant H. Richmeyer.—At a regular meeting of the Medico-Surgical Society, held Friday, May 20, 1904, the following resolutions were adopted:

Whereas, The society has learned with deep regret of the death of Dr. Grant H. Richmeyer on the 21st of April last,

Resolved, That the profession as well as the society has lost a valued member, whose genial character as a man and ability as a physician was esteemed by all his associates,

Resolved, That a copy of these resolutions be transmitted to his family as an evidence of our respect and of our sincere sympathy in their affliction; and that they be published in two of the Medical journals of this city. Robert J. Devlin, J. D. Nagel, Henry Griswold, *Committee*.

Obituary Notes.—Dr. Bryan Gilmore Williams, late assistant physician to the Long Island State Hospital at Kings Park, died at sea on May 13. He was a graduate of Bellevue Hospital Medical College in the class of 1893. Dr. Williams was held in the highest esteem by his colleagues, both as a co-laborer and as a sincere friend. His sympathetic attention and genial good nature added much toward the betterment and for the happiness of the patients under his charge. At a stated meeting of the medical staff of the Long Island State Hospital, June 23, 1904, the following resolutions were adopted:

Resolved, That we learn with feelings of deepest sorrow of the death of our late associate, Dr. Bryan G. Williams, which occurred at sea May 13, 1904.

Resolved, That we desire to express to the family our sincere sympathy in this hour of sad bereavement.

Resolved, That a copy of these resolutions be sent to his relatives and for publication in the medical journals, and filed with the records of this hospital.

Dr. Mary E. Partridge of Bennington Vt., was drowned in Lake Champlain, near Bennington, on June 29. She was a graduate of the New York Medical College and Hospital for Women in the class of 1884.

Dr. Thomas Flint, a native of New Vineyard, Me., died on his ranch, near San Juan, Cal., June 19, in the eighty-first year of his age. He was a graduate of the Jefferson Medical College in the class of 1849. He had lived in California since 1851, was a member of the State Medical Society and of the American Medical Association, and had taken an active part in all public affairs, serving at one time in the capacity of State senator.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

HOSPITAL SUNDAY—PYOPNEUMOTHORAX—ELASTICITY OF AORTA—A NURSING HOME COMPANY—ANÆSTHETIZED CATS—SIR OLIVER LODGE ON EDUCATED MEN—WHAT IS BRANDY?—OBITUARY.

London June 17, 1904.

Hospital Sunday has come and gone. The most striking event in it was the discourse of the Bishop of Stepney at St. Paul's Cathedral. He made it the opportunity of reproving the rich and pleasure-loving people of the metropolis. Into the season—which he described as the festival of wealth and pleasure—he described hospital Sunday as coming as a shadow of suffering "and in the name of the poor of awful London" crying aloud, "Give an account of thy stewardship." He declared the love of money was spreading without the least increase in the sense of stewardship, and quoted a distinguished diplomat, who, after many years abroad, said, "When I left London and went out of London society it was indeed exclusive and somewhat selfish, but it was under some sort of control; I return to find it a rabble, devoted to the worship of money and what money can buy." The craving for pleasure has become a disease, said the bishop—a disease manifesting itself in a want of consideration for others that would never be possible in a healthy mind. He instanced ladies at the stalls of charitable bazaars with beautiful dresses not paid for, the unpaid bill meaning to the poor dressmaker, harrassed for want of capital, the loss of home and the support of aged parents or invalid sisters. To this indictment the bishop added, "I speak of what I know," and went on to declare that the disease was as ripe in the middle classes. There were some, he said, who talked of throwing the hospitals on the rates. "If that came to pass," he concluded, "the last tie which binds the wealth of London to the spirit of stewardship would be snapped." Something might certainly be said in reply to the bishop's heavy indictment, but it would not hurt the fashionable congregation, and the wealth of the city has always been ready to assist.

On this occasion the collection at St. Paul's amounted to £5,000, and there are many other churches which appear to have given in accordance with their means. It is too soon to say whether the collection will this year be larger than last, but it seems probable.

Professor Finlay of Aberdeen read notes at our Clinical Society of a case of pyopneumothorax in a boy of seventeen admitted into the Aberdeen Infirmary with tuberculous pneumothorax on the left side. Resection of ribs was practised on three occasions, and the lad was treated for many months in the open air on the balcony of the ward. He was enabled to resume his work as a gardener, but there was still a discharging sinus. The tuberculous process at the right apex, which was also present at first, was arrested, but the urine for some time has contained albumin, suggesting further operation. Professor Finlay mentioned another case similarly benefited and one which had not improved by evacuation of the pus. He thought radical treatment better than repeated tappings or leaving the fluid alone, especially in view of the modern treatment of tuberculosis.

Dr. Parkinson said the late Dr. Fagge had had several cases of recovery without operation, and asked if it was desirable to resort to it for so slight a benefit. Dr. P. Kidd said we should not be too much influenced by the older methods; the chief difficulty was to determine the extent of the disease.

The elasticity of the aorta has been the subject of careful research by Drs. Herringham and W. H. Wills, who have communicated their results to the Medico-Chirurgical Society as a contribution to the study of arterial sclerosis. These are some of the conclusions: The width of the vessel increases with age as the result of internal pressure; the more it is dilated the less it can be further stretched; after stretching it returns to its original volume; elasticity depends chiefly upon the tunica media and loss of it in changes in the same coat, and this coat increases in substance with age, due to connective or elastic tissue or both; the muscular tissue does not seem to vary.

Dr. Clifford Allbutt expressed general interest in the subject, and said his own opinions were corroborated by the research that a large class of arterial disease was consequent on high blood pressure.

Dr. Auld said that he and the late Professor Coats had found that in some cases the elastic laminæ underwent granular degeneration confined to the smallest fibers. Such a change might account for lessened elasticity, and it would be reinforced by any increase of connective tissue which would interfere with the elastic fibers.

Dr. Morrison thought there was some muscular hypertrophy, and Dr. Finlay hoped the authors would extend their researches to the arteries of patients affected with syphilis and alcoholics.

Dr. Seymour Taylor suggested extending the research to arteries that are naturally tortuous. He had thought that arteries were tortuous from being in movable tissues. The splenic might be compared with the radial.

Sir D. Powell said widening of the aorta reached its greatest degree about the age of forty, just when the stress of life at full pressure begins to tell. Clinically loss of elasticity of the aorta does not seem to be connected with cardiac hypertrophy.

A company is being promoted to provide a nursing home at moderate charges. The existing homes are so expensive that the middle classes can scarcely afford to enter them. They are, too, mostly the appanages of particular surgeons. Nor is it only the fixed price per week that proves deterrent. The extras rival the most sumptuous hotels, though without their luxurious appointments.

The new company has secured the option of a fine block of buildings in Mandeville Place, an excellent position for the purpose, close to several professional localities. The proposal is to charge £2 2s. per week for board, lodging, and nursing. No visiting staff is to be appointed. Patients will arrange with their own medical men, will only be admitted on the recommendation of their usual attendants. There will be a house surgeon on the premises for emergencies and to carry out the treatment of patient's own doctors.

Among the exhibits at the University Converzasione a loan collection of cats excited considerable attention. They were passing their time under chloroform. Dr. Waller, F.R.S., on the program, remarked that "the accidental deaths under chloroform used for surgical anæsthesics are principally due to fluctuations in the chloroform percentage. The cats exhibited are spending the evening under one per cent. of chloroform and air pumped into the bell-jar by a Dubois pump, which is occasionally turned to keep up the supply. The cats are to return intact to their homes."

One lady visitor was overheard to say "what dreadful headaches the poor things will have to-morrow." I commend the remark to the antivivisectionists.

Sir Oliver Lodge has given offence in some quarters by remarking in a review that certain ideas cannot be made "so childishly simple as to be apprehended by the general average of so-called educated men in this country, whose sense-perceptions in the direction of great and comprehensive ideas have not been developed." It is rather a hard saying, but I do not suppose he meant it to be offensive, though his critics are not slow to retort that the attitude of scientific men is too often one of contempt for others, and is responsible for much of the indifference of ordinary educated persons to their work. One admits there is insufficient appreciation of science, but adds there is also a "very marked absence of those great expositors of science who have forced their discoveries and theories on the attention of the so-called educated men of their time." This Roland for an Oliver is not undeserved in the light of the proceedings of the late meeting of the International Association of Scientific Societies and Academies, which at its first meeting resolved to exclude the press.

What is brandy? That question meets us just now in many newspapers and circulars. It was started by a prosecution of a person for selling as such a liquid containing 60 per cent. of spirit not obtained from the grape. Analysts have usually been willing to certify as genuine any spirituous liquor of a certain alcoholic strength, but now the origin of the alcohol is to be taken into account. The magistrate accepted the definition of the pharmacopœia. The medical value of brandy is thought by many to depend on the ethers, but others think it does not differ from whiskey or other spirits, and they attribute all the effects of all these liquors to the amount of alcohol in them. It can certainly be plausibly argued that the alcohol must overshadow the small amount of ethers. In the Oliver-Sharpey lectures lately delivered by Dr. Oliver, he mentioned that the effect of alcohol on the blood pressure is modified by other constituents of wines, etc. The magistrate's decision on the case cited has set the advertising wine and spirit dealers to work with circulars, etc. From the agents of one I have received no less than twelve circulars, besides as many letters. It seems an extravagant way of advertising.

Brigade-Surgeon W. F. Colliott, late of the Royal Army Medical Corps, died on the 8th inst., aged sixty-five. He entered the army in 1862, had charge of the cholera camp in India in 1867, served in the Afghan war 1878-80, for which he held the medal. Retired in 1899.

Surgeon-General W. Thorn, I. M. S., died in his eighty-fifth year on the 12th inst. He retired in 1877.

Richard J. Dearden, J. P., of Manchester, died on the 11th, only forty-nine, from blood-poisoning following extensive cellulitis contracted at a post-mortem, which he undertook for a friend, and which within a week brought him to his death. He took the M.R.C.S. in 1879 and became House Surgeon at the Royal Infirmary and soon after entered private practice. He was divisional surgeon to the Manchester Police.

OUR VIENNA LETTER.

(From Our Special Correspondent.)

OBSTETRIC PARALYSIS—COMBINED GRAVES' DISEASE AND ADDISON'S DISEASE—FUNCTION OF THE PARATHYROID GLANDS—SIGNIFICANCE OF BLOOD IN THE STOOLS—EXSECTION OF THE TRACHEA FOR CANCER OF THE THYROID—HOCHENEGG IN THE CHAIR OF SURGERY—A CHAIR OF RADIOLOGY.

VIENNA, June 10, 1904.

At a recent meeting of the Pediatric Society, Dr. Zappert presented a two-year-old child with bilateral obstetric paralysis. At the age of six months there was paralysis affecting the deltoid, biceps, supraspinatus, and prachialis anticus. The finger movements were free, but the arms hung powerless, were rotated inward, could not be raised, and movements of the elbow-joints were impossible. Under massage and faradization, the paralysis gradually disappeared, until at present there remain only an inward rotation and an atrophy of the deltoid. The case is worthy of note because a bilateral obstetric paralysis very rarely occurs.

In the Society of Psychology and Neurology, Dr. Hirschl presented a case which gave the symptoms both of Graves' disease and of Addison's disease. The patient was a brewer, thirty-six years old, who had been ill since August, 1903, and who first came to the clinic in the following November. Tremor, excessive sweating, and diarrhœa marked the onset. At the beginning of October, the patient noticed exophthalmos, and complained also of palpitation. The most noticeable symptom was extreme emaciation. From the middle of August to the 23d of November his weight fell from 90 to 58 kilos (198 to 128 pounds). Along with the emaciation, went a high grade of motor weakness and progressive excitability. At the beginning of October, bronzing of the skin began, which reached its height at the time of the man's first appearance at the clinic. Examination then showed, on the one hand, loss of motor power, bronzing of the skin but with no pigmentation of the mouth, excitability and forgetfulness; on the other, struma, exophthalmos with the three eye symptoms, palpitation, and tremor. His weight was 58 kilos (128 pounds); blood pressure, according to the tonometer, 100; microscopical blood examination normal; hæmoglobin, according to the von Fleischl hæmoglobinometer, 70 per cent.; and glycosuria. At the beginning he had vomited excessively, and later had had diarrhœa. There were no physical signs of tuberculosis in the patient, but his mother and first wife had died of tuberculosis.

Dr. Pineles has made known some recent discoveries in regard to the physiology and pathology of the thyroid gland and the parathyroids. The fact that after operations on the thyroid in which the parathyroids are left, no tetany ensues, while after total thyroid extirpation, including the parathyroids, tetany is the rule, makes the assumption natural that there is a causal relation between the removal of the parathyroids and the development of tetany. Experiments on animals, namely monkeys and cats, have confirmed this opinion. These experiments showed that total thyroid extirpation, or the removal of the parathyroids alone, is followed by tetany, while the removal of the thyroid, the parathyroids being retained, leads indeed to cachexia, but not to tetany. The results of operations on man are also confirmatory. After extirpation of a tongue tumor which had developed from a thyroid displaced upward, tetany did not follow, because the parathyroids, derived from the third and fourth branchial clefts, remained, and were not extirpated. In like manner tetany occurs less often after resection of the isthmus than after that of both lobes, because the parathyroids in the capsules of the lobes remain.

In the General Medical Society, Dr. A. Loebl spoke concerning a new way of detecting the presence of blood in the fæces, and of its diagnostic significance. Loebl proved its presence in the following way: First, the stool was examined in its original condition for fat; if it contained much fat, this was next extracted with ether; the remainder, or the stool not rich in fat, was set aside with acetic acid until it was of the consistency of thick soup, or, in the case of a hard stool, a little concentrated acid was added. To 3 c.c. of this mixture was added an equal quantity of ether, and the whole allowed to stand for twenty-four hours. The extract was then divided in two parts of 3 c.c. each: to the first was added freshly prepared tincture of guaiacum (a solution of guaiacum in ether), to the second, a solution of Barbadoes aloes in 60 per cent. alcohol, and, finally, to each, peroxide of hydrogen. After a minute, the portion with the tincture of guaiacum becomes blue, the color disappearing after about fifteen minutes; in the second portion, the color appears later, but is permanent. Dr. Loebl has, by this method, examined the stools of 115 patients. The stools of twenty patients with tuberculosis of the lungs, who came to autopsy, were examined during life for the presence of tubercle bacilli and for blood; nine cases showed ulcers of the intestine at autopsy, and of these, six showed tubercle bacilli and blood in the fæces during life, and three either one or the other: of the remaining eleven cases, examination had shown tubercle bacilli in seven, and neither bacilli nor blood in four.

The presence of tubercle bacilli and blood in the fæces is diagnostic of intestinal tuberculosis. In the case of a patient who suffered from gastric ulcer during the attacks of epigrastric pain, blood was continually found in the stools, and because of the persistence of this symptom, the ulcer was closed. The operation confirmed the diagnosis. In typhoid fever, by the above method, slight bleeding could be detected, and, by the adoption of adequate measures, a greater hemorrhage could be stopped Further, blood has been found in the fæces in cases of intestinal parasites, tetany from autointoxication, and in two cases of cholelithiasis. Prof. Arthur Schiff stated in the discussion which followed that, according to the investigations of Boas and Hartmann, concerning the appearance of blood in the fæces, a prescribed diet must be adhered to. Otherwise blood from flesh food might be mistaken for hemorrhage from the intestine. Schiff asked for further information in regard to the presence of blood in cases of tetany and cholelithiasis. Loebl answered that through very recently published investigations the fact has been established that no blood is detected in the fæces after the eating of even very large quantities of cooked meat. Many of the patients examined by him were, however, on a milk diet. On the other hand, after the use of the modern preparations of iron, blood is found in the fæces, while this is not the case after the use of the official preparations. Blood in the stools of patients suffering from tetany comes from small hemorrhages following erosions, and is dependent on the accompanying catarrh. In cholelithiasis, the vulnerability of the vessels is well known, and hemorrhage readily occurs.

In the Society of Physicians, Professor von Eiselberg presented a patient who had been operated on for carcinoma of the thyroid, the operation including circular resection of the trachea, followed by suture. The defect on the anterior wall of the trachea after the sloughing of the suture was covered by a flap of periosteum taken from the sternum.

In 1898 a man, forty-four years old, having had trouble with his neck since his eighth year, was operated on at the Albert clinic for colloid struma. In 1900 the goiter returned, and increasing dyspnœa drove the patient, in 1902, to the Schrötter clinic, where tracheotomy was done. Through examination of an excised portion, diagnosis of adenocarcinoma of the thyroid was made. At first there was improvement, then the carcinoma increased in size through the trachea to the level of the fistula, when again extreme dyspnœa appeared. In January, 1904, the patient was admitted to the surgical clinic, and a large, hard, swollen thyroid was found, holding the trachea in its grasp. On January 11, 1904, Professor von Eiselberg undertook the extirpation of the tumor, for which it was necessary to resect 4 cm. of the trachea. Circular suture followed, after the insertion of a cannula. The stitches sloughed in the anterior half, and the defect was first covered provisionally with a celluloid plate, and afterward with a flap of periosteum from the sternum. This required two sittings, the first, February 19, and the second, March 5. A small endolaryngeal mass of granulation tissue was afterward removed at the Schrötter clinic. Thus, through combination of the ideal methods, resection and suture, a good result was obtained.

On May 13 Professor Hochenegg took charge of the Gussenbauer surgical clinic, which has won so high a reputation through his predecessor, Billroth. Hochenegg, who, as a pupil of Professor Albert stands in known opposition to the teachings of Billroth, at his inauguration for which had gathered all the surgeons and almost the whole Vienna faculty, honoring his predecessor, called to mind and commended the service he had done to surgery. Hochenegg's address related to the treatment and transmission of carcinomata, the topic which up to the present time has formed a large part of the study of this clinic.

Another event of this month was the establishment of a

chair of radiology, the first on this continent. It is occupied by Dr. Kienbock, Dr. Freund, and Dr. Holzknecht, and their appointments were confirmed by the Emperor. All three have worked as pioneers in Austria, on the subject of radiology, and it remains now to be seen into what this youngest branch of our science will develop.

THE PRESENT STATUS OF THE SURGICAL TREATMENT OF CHRONIC BRIGHT'S DISEASE.

To the Editor of the Medical Record:

Sir: In your issue of July 2, 1904, appears a letter from Dr. Edebohls, bearing upon my article, "The Present Status of the Surgical Treatment of Chronic Bright's Disease." I hesitated to answer this communication, the tone of which warrants the belief that the writer considered my contribution to this interesting subject as a criticism of his views and practices, while in reality its prime and sole object was to develop and establish the indications for, and the limitations of, the rational employment of surgical therapy in cases of chronic nephritis.

Dr. Edebohls emphatically states in his letter that his patient, Mrs. C. B., whose history I quoted in abstract in my paper, suffered from *chronic parenchymatous nephritis, upon which a bilateral pyelonephritis with miliary abscesses was engrafted*, whereas I claimed that the kidneys of this patient presented simply the lesions of *a bacterial* (or *septic*) *nephritis*.

Here are the pathologist's reports (page 967): "*Right Kidney.*—The large right kidney, riddled with innumerable abscesses and with its pelvis filled with pus, showed, on microscopical examination, *typical, histological characteristics of multiple abscesses*. In the abscess areas there was found a thick bacillus corresponding morphologically to a species of the proteus, a class frequently responsible for *suppurative nephritis*." *Left Kidney.*—There is no description of its gross appearance, but microscopical examination of the small piece of renal tissue removed from the kidney showed "*decided histological evidence* of multiple foci of *nephritis of infectious* (*septic*) *type*. As far as was possible to determine from the minute size of the cortical issue received, these foci were confined to the areas corresponding to terminal arteries and consequently had a wedge-shaped outline. In the diseased areas, the tubules presented granular and partially disintegrated epithelia, often detached from the membrana propria, and the lumina were not infrequently occluded by polynuclear leucocytes (pus), fragmented epithelia, blood cells, and amorphous detritus. Some tubules were filled with dense hyaline material (casts)."

Where in these reports are the gross or microscopical evidences of chronic parenchymatous nephritis? Was I not right in my statement that these kidneys showed only the lesions of infectious (bacterial) nephritis? Our criterion in these cases is the pathological findings, and from these I drew my conclusions. Upon what evidences does Dr. Edebohls base his diagnosis of chronic parenchymatous nephritis in addition to the infectious (bacterial) nephritis?

As to my statement that Mrs. C. B. "finally succumbed to the disease," I regret exceedingly that in arranging the material which was to be employed in my paper, this patient was recorded as having died. Such errors are bound to occur in handling so large a number of cases from the literature, especially when the patient's final outcome must be sought for in different numbers of the medical papers. But while this patient's recovery is most happy for herself and friends, and most important for Dr. Edebohls' statistics, it has no significance at all as regards the arguments in my paper. I consider this case as one of bacterial nephritis, and concerning the value of surgical therapy in this type of chronic nephritis, I stated on page 096: "The bacterial nephritides of chronic character are at times favorably influenced by operation." Of Rovsing's eight cases, seven were cured and one was improved.

It is thus seen that recovery in the bacterial form of chronic nephritis has been the rule, and I am most happy to learn from the doctor that his patient is so far doing well, and I regret the error which occurred in the tabulation.

From the above it is evident that the validity of my deductions and conclusions are not nullified by the incorrectness of the premises upon which they are based (letter, page 26), but rather show that the study of this case before the operation upon the second kidney was incomplete, for a culture of the urine of the left organ drawn by aseptic ureteral catheterization would probably have revealed the infecting organism and so have led to a correct ante-operative diagnosis.

The incongruity of the criticism of Dr. Edebohls concerning avoidable errors on my part will appear at once to him who reads the doctor's writings and reports of cases and fails to find therein any mention of a systematic practice to determine by aseptic ureteral catheterization and culture from the urine obtained in this way, the nature and causation of a chronic nephritis, and who misses in his publications the routine practice of experienced kidney surgeons of determining the combined and individual functional sufficiency or insufficiency of the kidneys by the absolute scientific means which ureteral catheterization and cryoscopy have put at our disposal, before proceeding to operation upon these organs.

Anomalies of Thyroid Secretion.—Frederick C. Shattuck gives a most interesting paper on the evolution of our present knowledge of thyroid function, reviewing step by step the advances that have been made in the knowledge and treatment of thyroid affections in recent years. Whether the action of the thyroid and parathyroids is antagonistic, complemental, or unrelated, we do not yet know. But the evidence so far does not seem to indicate a vital causal connection between the parathyroids and Graves' disease. The whole treatment of myxœdema is practically comprised in the administration of thyroid extract. It is safer to begin with moderate doses, from 3 to 5 grains, twice a day for an adult, increasing the dose in size, frequency, or both, as the tolerance of the patient is developed. The treatment of Graves' disease has long been unsatisfactory at the best. The diet should consist mainly of fats, starches, and sugars, with great moderation in or abstention from highly nitrogenous food. Rest and quiet are most advisable. A cool summer resort is very important. The bowels should be carefully looked after. The bowels are apt to be either constipated or relaxed. Diarrhœa may be treated by some form of bismuth. Calomel, once or twice a week, has been used with success in cases of constipation. Neutral bromide of quinine has brought about normal defecation both in cases of diarrhœa and of constipation. This drug, the writer has found more helpful than any other he has ever used. The toleration of quinine in Graves' disease is remarkable, and is seemingly proportional to the severity of the symptoms. If these measures are not followed by distinct improvement operation is to be seriously considered in severe cases.

Journal of the American Medical Association, July 2, 1904.

Dysentery; A Report of Several Cases in Which Bacillus Dysenteriæ (Shiga) Was Found in Washington, D.C.—Louise Taylor-Jones concludes that Washington, D. C., is included in the geographical distribution of *B. dysenteriæ* (Shiga). The Shiga bacillus, both alkaline (Shiga) and acid (Flexner) types, is found in that city both in adults and children suffering from dysentery. An alkaline type found in one case was a slight variation from the type, in that in three days in glucose agar, not first made sugar-free, the bacillus produces a slight amount of gas, whereas no gas is produced with the sugar-free glucose agar. None of the other Shiga bacilli at hand produced gas in this same medium.

Lumbar Abscess: Report of Six Cases Treated by Aspiration and Injection of Iodoform-Glycerin Emulsion.—Alfred Irving Ludlow made this clinical report and summarized as follows: (1) Four cases gave a family history of tuberculosis. (2) Five cases occurred in females whose ages ranged from seven to thirty-nine years and one case in a male twenty-five years old. (3) Two patients gave a history of injury to the back. (4) In three cases two aspirations were made, in one case three, in another four, and in another ten. (5) The urine from four cases out of six gave a reaction for iodin the next day after the aspiration. This reaction persisted only for two or three days, except in one case in which it persisted for two weeks. (6) Slight mental depression was noticed in two cases. (7) As a general rule, there was an elevation of temperature from two to four degrees following each aspiration. (8) The cultures were sterile in every case except one, in which *Bacillus proteus vulgaris* was obtained. (9) In all the six cases there has been no indication of return of the abscess after a period of five years in one case, three years in another and two years in a third, while in the remaining three, one year or less has elapsed since the last aspiration. There was a marked improvement in the general health of every patient.

Medical News, July 2, 1904.

Diagnosis and Treatment of Internal Hemorrhoids.—H. A. Bray concludes that (1) In the treatment of internal hemorrhoids, it is important, in the first place, to de-

termine whether the disease is primary or secondary to some affection of the pelvic organs. (2) In the first stage of hemorrhoidal disease no operative treatment is indicated. (3) The true value of the non-operative treatment is frequently underestimated in the second stage of hemorrhoidal disease. (4) None but operative treatment should be resorted to in the third stage of hemorrhoidal disease.

Primary Myokymia; with Report of a Case.—Robert M. Daley defines myokymia as a disorder characterized by fibrillary and wave-like contractions of the individual fibers of various muscles of the body without locomotor effect. Usually it appears as a minor symptom, in diseases of toxic origin, such as lead and mercurial poisoning. It is also seen in neurasthenia and in sciatica. It may occur as the only morbid condition. Of the cases previously reported, all save two, have been among the laboring classes. All of these cases were males, the ages running from twenty-one to seventy-one years. In two, the legs only were affected; in the remainder, the legs and arms or legs and entire muscular system, excepting in one instance, the hands, and in another, the face and neck. None show atrophy of the muscles or much disturbance of the general health. Nearly all complain of general pains, indefinite in character, and also of becoming easily tired. Four cases were cured and improved by rest, galvanism, and warm baths. Of the pathology nothing is known. The writer reports a case of this nature.

A Consideration of the Question of Drainage in Cases of Acute Appendicitis with Spreading Peritonitis.—Lucius Wales Hotchkiss believes that he has amply demonstrated the great value of the smaller incisions, of the location and removal of the appendix largely by the sense of touch, which does away with over much exposure and handling of the intestines and of the free irrigation of the peritoneum with hot normal salt solution, depending upon this rather than drainage and the removal of the diseased appendix in every possible case. This practice is a radical departure from the method formerly employed. The power of the peritoneum to deal with infection is marvelous. In acute progressive appendicitis, nature strives to wall off the diseased organ by a barrier of plastic exudate and throws out a powerful second line of defense against general infection by bringing about marked hyperleucocytosis. In the case of the gangrenous appendix, however, the task is, as a rule, too much for the natural physiological processes to accomplish unaided. The first thing to do is to remove the focus of infection, the appendix, and to do it so as not to cripple the inherent power of the peritoneum to deal with such toxic products as must necessarily be left behind. The writer states that during the past few years he has grown to rely almost wholly upon the flushing of the peritoneal cavity with hot normal salt solution, rather than upon any method of external drainage. The writer believes that the drain has practically been eliminated as a factor of any importance in the treatment of spreading peritonitis, excepting so far as it acts as a drain for the external wound, which, in most of these cases is an infected wound and heals by granulation. The writer agrees with Clark and Norris in their conclusions that the use of salt infusions does not increase, but minimizes the danger of pyogenic infection; and in addition to the reduction of mortality, the convalescence of the patient is rendered infinitely more comfortable and satisfactory through the reduction of thirst, the increase in the urinary excretion, and the minimizing of vesical irritation.

New York Medical Journal, July 2, 1904.

X-ray Therapeutics.—G. H. Stover relates fifty-one cases which in part indicated the main features of the work being done by the *x*-ray. Lupus erythematosus is more slowly amendable to treatment by the *x*-ray than are other forms of lupus. So uniform has been his success in the treatment of epithelioma that he believes the *x*-ray to be a specific for this condition. In carcinoma the results have not been so gratifying. His results in the treatment of bone tuberculosis has been gratifying. In certain diseased conditions the effect of the *x*-ray was very satisfactory, even brilliant, yet for a long time to come great caution should characterize our utterances to patients. He regretted the rash manner in which many who were totally unfitted were pushing into *x*-ray work. He believed that after a while there was going to be a reaction against the *x*-ray as a therapeutic measure, and he hoped the pendulum would not swing too far, casting undeserved discredit on a therapeutic agent that has established a rightful place for itself.

Hermann Brehmer, and the Semi-centennial Celebration of Brehmer's Sanatorium for the Treatment of Consumptives (July 2, 1854-July 2, 1904).—S. A. Knopf believes that a fitting tribute to the founder of the first sanatorium in the world for the exclusive treatment of patients afflicted with pulmonary tuberculosis and the best known promulgator of modern phthisiotherapy may well be paid on this occasion from this side of the Atlantic. Hermann Brehmer was born in Kurtsch, Province of Silesia, Prussia, August 4, 1826. He attended the Elisabeth Gymnasium in Breslau, and after receiving his classical degree went to the Universities of Breslau and Berlin, studying natural philosophy and mathematics. He was so attracted by the lectures of Johannes Miller, the great physiologist, that he decided to study medicine instead of mathematics. He began to practise in the little village of Goerbersdorf which, at that time, had no more than 900 inhabitants. Owing to the intervention of Humboldt and Schoenlein, he received concession from the government to build his sanatorium. It had a small beginning, but its success was marvelous, and to-day it is the largest private institution of its kind in the world, and can accommodate about 300 patients. Brehmer died December 12, 1889, when the sanatorium movement was hardly in its infancy. At the time of his death there were three sanatoria in Germany, while now there are hundreds. In the United States there are now 135 institutions already in operation or projected.

The Results of X-ray Treatment.—Samuel Beresford Childs concludes from his own experience and that reported by others: First: The therapeutic field of greatest usefulness of the *x*-ray is with superficial epitheliomata, rodent ulcer, and lupus vulgaris, when the area involved is conspicuous, as on the face or neck, and where a cosmetic result is particularly to be desired. Second: Healing by the *x*-ray leaves the smallest and least perceptible scar; for, when properly applied, it destroys only diseased tissue, and particularly commends itself for use in those localities where it is undesirable to sacrifice the surrounding tissues. Third: The *x*-ray is very efficacious in many obstinate cases, which have resisted the ordinary methods of treatment, such as acne rosacea, chronic localized patches of eczema and psoriasis, lupus erythematosus, and kindred skin diseases. Fourth: The results in tuberculosis glands, when no suppurating focus is present, are encouraging and the enlarged mass of glands in Hodgkin's disease appear to be susceptible to the treatment. Fifth: The *x*-ray should not be employed in any operable, deep, malignant growth, with two exceptions: First: as pointed out by Coley, where a surgical operation would sacrifice an extremity, and even in this case the value of the *x*-ray is uncertain, and is determined by a few weeks' trial. Second, as mentioned by Pusey, with a view to limiting the operation by checking the growth when immediate operation is inadvisable. Sixth: The *x*-ray may be of service even in inoperable malignant growths, by relieving pain, diminishing discharges, and lessening their offensiveness, and in many cases life may be prolonged in comparative comfort for a considerable period of time. Furthermore, from these apparently hopeless cases a number of remarkable improvements and a few recoveries have been reported. Seventh: The *x*-ray should be used as a prophylactic against return after all operations for the removal of deep malignant growths. Eighth: The area of exposure should be wide, and the intensity and quality of the rays should be adapted to each case.

American Medicine, July 2, 1904

Measurements of Blood-pressure in Fevers Before, During, and After the Administration of Strychnine.—Richard C. Cabot declares that among those cases studied were 31 of typhoid fever, 4 of pneumonia, and 15 others with a variety of diagnosis. In 32 cases the strychnine was given by mouth, and in 18 subcutaneously. The total daily dose was usually 1/8 grain. The measurements were taken with Stanton's modification of the Riva-Rocci instrument. The observations extended over about eight months, and include over 5,000 measurements. The total result is negative. The writer cannot see that strychnine exerts any influence upon the blood-pressure in febrile cases, when given in the manner and dose as mentioned. In the 24 hours following the administration of the drug there was a rise of 5 mm, or more of pressure in 16 cases, a fall in 17 cases, and no change in 24. The average pressure in the 50 cases that received a daily dose of strychnine was no greater than in 18 control cases without any drug. While strychnine and whiskey seemed to be entirely without influence upon the blood-pressures, the sight of the dinner tray or the prospect of getting up produced a most obvious, though transient, rise in the pressure. The writer concludes that in the dosage used, strychnine does not raise or in any way effect the maximum or minimum blood-pressure so far as can be determined by the instrument employed.

Tuberculosis As It Affects the Skin.—M. B. Hartzell declares that the most frequent form of skin disease due to the tubercle bacillus is lupus vulgaris. It is possible to demonstrate the presence of bacillus tuberculosis in lupus tissue, but this organism is scanty in numbers. This disease may also effect the nasal, buccal, laryngeal, and vaginal mucous membranes. "Tuberculosis verrucosa cutis" is closely related to lupus vulgaris in some of its features. Identical with verrucose tuberculosis is the so-called anatomic wart, verruca necrogenica. One of the earliest recognized forms of tuberculous affections of the skin is the tuberculous ulcer, known also as miliary tuberculosis of the skin. It is usually found about the orifices of the body, and is in the great majority of cases secondary to tuberculosis of other organs. It may, however, occur upon other parts, and it may occur as a primary lesion, and be followed by visceral tuberculosis. Scrofula is but a manifestation of tuberculosis. It gives rise to a number of skin lesions, usually ulcerative, to which the name serofuloderms has been given. The commonest form of scrofuloderm is the chronic ulcer which occurs so often in connection with tuberculous adenitis, especially in the region of the neck. In all of these affections, the presence of bacillus tuberculosis has been demonstrated with more or less certainty. Another class of eruptions is seen in individuals who either in themselves or in the members of their families show a more or less clear history of tuberculosis, but in which all efforts to find the tuberculous organism have failed, although the tissue changes are such as are present in tuberculous disease. The constitutional treatment of tuberculosis of the skin differs in no respect from that of tuberculosis of other tissues.

The More Remote Consequences of Infectious Bile.—John B. Deaver calls special attention to these three conditions—pancreatitis, biliary cirrhosis, and adhesions of the gall-bladder to various of the surrounding viscera. Seventeen cases of acute pancreatitis have been reported, eleven of which were accompanied by calculi in the biliary tract. A considerable number of cases do occur, however, in which gallstones are absent, and should be carefully studied, for gallstones do not always induce acute pancreatitis. Especially must the inference of microorganisms be considered as causative factors in obstructing the pancreatic ducts. Bacteria may not only infect the retained secretion, but may also by direct continuity ascend from an existing gastrointestinal catarrh. Chronic pancreatitis is also often due to some obstruction of the duct of the pancreas by gallstones. This is especially striking when the biliary calculus is large, and so situated that the duct of Wirsung is occluded without the entrance of the bile into the pancreas. The diagnosis of pancreatitis is often very difficult. In general, when an individual from whom the history of a previous gallstone colic may or may not be elicited, is suddenly seized with severe epigastric pain, nausea, vomiting, rapid pulse, dyspnœa, and cyanosis, followed by a rapid loss of strength, the diagnosis is acute pancreatitis. The early symptoms strongly resemble those of intestinal obstruction, and the exhaustion and collapse are often so severe as to induce death within forty-eight hours. The pain is colicky in character. Chronic pancreatitis, due to gallstones, is often hard to recognize. It is only by grouping both the clinical and the laboratory findings that the disease of the pancreas may be accurately and satisfactorily studied. As to biliary cirrhosis, the writer states that in the great majority of common-duct obstruction cases for which he has operated, a bacteriologic investigation of the bile has revealed the presence of some microorganisms, the colon bacillus, the typhoid bacillus, the staphylococcus, or the streptococcus. He believes that as complete bile stasis rarely occurs in common-duct obstruction, infection must exert a positive influence in the cirrhosis. Adhesion of the gall-bladder or ducts to surrounding viscera will follow nearly all severe inflammations of the gall-bladder from a pericholecystitis and embarrass the functions of the contiguous organs involved by the adhesions. The typhoid bacillus is a most fertile factor in the production of acute or chronic biliary tract disease, or in the causation of gallstones. But the first place in the rôle of gallstone producer must be credited to the colon bacillus. The entrance of bacteria into the biliary tract is possible by three ways: They may ascend the bile ducts from the duodenum, are deposited by the general circulation, or reach the ducts and gall-bladder by means of the portal vein.

The Lancet, June 25, 1904.

Notes on Three Cases of Intestinal Obstruction.—G. Reinhardt Anderson makes a record of three cases of intestinal obstruction which were instructive as they illustrated the necessity of caution before expressing an opinion on conditions leading to the obstruction. The first case was one with an unsuspected obturator hernia occurring in an elderly woman. In the second the small intestines were so matted together that obstruction, which had been incomplete for some time, became suddenly complete, and for this condition lateral anastomosis had to be performed. The last case was one of chronic obstruction due to inflammatory exudation in the pelvis, necessitating a temporary colotomy for its relief.

A Case of Mania from Traumatic Meningitis; Recovery after Trephining.—Charles Brook reports the case of a man, twenty years old, who struck his forehead violently on the bottom when diving. He was not rendered unconscious, but went home complaining a little of his head. His manner changed from that day and he became irritable and excitable and within one month had paroxysms of violence. Six months later he was placed in an asylum. Six weeks later Dr. Brooks saw him and found a distinct swelling on the right frontal bone, rather red and somewhat tender. Trephining was advised and performed. The bone was rather thin and very hard and white, with no diploe. The dura was opened and three ounces of clear serum let out. The wound healed perfectly. Never from the time the patient recovered consciousness has he shown the slightest sign of mental disturbance.

The Prophylactic Use of Morphine in Cases of Severe Cerebral Injury.—J. A. MacDougall, in 1899, when he read a paper on "Meningitis," by Dr. Barr of Liverpool, realized how freely morphine might be given in this disease, how excellent were the results attendant upon its employment, and how in all probability its beneficial action was brought about largely through its effect upon the vascular and nervous systems, inducing that condition of *rest*. Further and natural reasoning was this: if opium by its action on the nervous system quiets brain cells and lessens the functional activity of the nervous fibrils which connect them with one another, if it lessens pain and removes the effect of peripheral stimuli, if it contracts cerebral arterioles and through the cardiac ganglia renders the heart's action slower and vascular pressure less pronounced, then its effect upon a brain that is traumatically damaged and that demands quiet for its repair can only be beneficent. He had found that if after severe brain injury the patient was kept under the influence of morphine convalescence was more rapid and steady, grave cerebral symptoms had been wanting, and the continuous rise of temperature had been notably absent. A short record of cases was given to strengthen his contention.

British Medical Journal, June 25, 1904.

Hypodermic Injection of Quinine Sulphate.—G. F. Darker finds that ordinary quinine sulphate mixed with about one and one-half times its own weight of vaselin makes a suitable mixture to inject under the skin of the natives in West Africa to lessen the malarial index. A mass containing 15 to 20 gr. of quinine after injection takes about three and one-half months to absorb. During that time the writer has failed to find malarial parasites in the children on whom he has tried this mixture. An ordinary metal hypodermic syringe will suffice. The whole proceeding must be done under aseptic precautions. It is well to give at the same time a dose of quinine by mouth or an intramuscular injection of the same drug. The left side of the abdomen near the flank is the most suitable site for injection.

Acute Dermatitis Produced by Satin-wood Irritation.—H. E. Jones gives an account of two distinct outbreaks of acute dermatitis occurring among a number of joiners and cabinet-makers. The exposed parts are those affected. The first thing noticed is an irritation on the skin; later on the parts become hot and red, and subsequently become swollen and uncomfortable, and although not painful, the patient cannot sleep well. Still later the parts become moist and complete desquamation takes place. The first attack is rather slow in its onset, but relapses come on with great rapidity. After desquamation, the new skin would be more easily irritated than the old. The cause of this dermatitis seems to be irritation caused by East Indian satin-wood dust. As to treatment, it has been suggested that the men should remain off duty till the epidermis is fairly strong, and that then vaselin or some oily substance be smeared over the exposed parts while the men are at work.

Intrauterine Infection of the Fœtus in Smallpox.—James M. Cowie and Duncan Forbes speak of three cases they have seen of infants attacked with smallpox so soon after birth as to warrant the conclusion that they received the infection while still *in utero*. Considering the interval between infection and the appearance of the rash as the

usual one of fourteen days, the first child must have been infected on or about the date of onset of the mother's illness and three or four days before birth; in the second case the time must have been six days before the onset in the mother and seven days before birth, and in the third case five days before the mother sickened and seven days before birth. These children were all born about full time. Two other cases are mentioned by the writers: One was that of a woman in the seventh month of pregnancy who developed a discrete attack of smallpox. She was discharged from the hospital about a month after admission. The child was born about a month after discharge and showed no signs of having had smallpox. It was successfully vaccinated. Thus, no immunity was conferred on the child by the mother's attack. The other, a five-months fœtus born in the fourth week of the mother's illness, showed no signs of smallpox. The liability of the fœtus to smallpox appears to increase directly with its age.

Deutsche medizinische Wochenschrift, June 16, 1904.

Therapy and Prophylaxis of Chronic Malaria.—Bassenge reports two cases contracted in the tropics, in which the continued administration of quinine was without effect in inhibiting the attacks or in preventing their recurrence. One patient had taken a half gram every fourth day for almost a year as a prophylactic measure, and yet became infected with malaria, the parasite of which could be demonstrated in the blood with certainty after the reaction following the injection of tuberculin. In the other patient the prophylaxis was also inefficient and the quinine given subsequently had no effect. A blood examination had never been made and the type of fever was unknown. After this had been determined by careful examination to be of the quartan type and the quinine administered at the proper moment, the disease was cured. This shows the necessity of knowing exactly when to give the quinine, as in this case the drug had no effect, and brought on, moreover, an obscure series of nervous symptoms. Unless the microscopical examination is made, therefore, the ordinary clinical diagnosis of malaria is of little value.

Late Recurrences of Carcinoma.—Jordan believes that the question of complete recovery from carcinoma can only be determined after the lapse of another twenty or thirty years, when a series of observations are available which have extended over several decades. The reports of isolated cases which have remained free from recurrences for prolonged periods are not always conclusive, for, as the author's observations show, late recurrences even after fifteen years, are not uncommon. He claims that one of the main factors in determining recurrences is in the individual character of the growth, and this varies within wide limits. The first case which he reports is a carcinoma of the tongue, where a recurrence took place after nineteen years after complete operative extirpation. The lymphatics were not involved at either time, which may be taken as an indication of the more or less benign character of the growth. The other case was a mammary carcinoma which ran a chronic course and showed recurrences every few years for fifteen years. It seems that this also was a mild form of the tumor, with diminished proliferative energy, so that minute particles remaining occupied several years before attaining the size of a palpable nodule. The author thinks that the statistics thus far presented be subjected to a revision with this point in view, *i.e.* the late recurrences, it will be found that so-called cases of complete cure are merely cases with prolonged freedom rather than total freedom from recurrences. It is also necessary to distinguish between the tumors which recur rapidly and those which recur after the lapse of a longer period.

A Substitute for Both Ureters.—James Israel calls attention to a class of cases in which a congenital obstruction to the urinary flow may be followed by a hydronephrosis which may gradually attain a considerable size without the production of any symptoms, and then suddenly manifest its presence by the development of a severe acute illness. This may take the form of colic, due to the increasing tension in the sac, or of septic fever and renal pain, due to an acute infection of its contents. Both of these conditions were well marked in the author's case, in which, in a thirteen-year-old boy, there was a large hydronephrosis in each kidney due to congenital disturbances, which was not detected until colic on the right side, and an acute infection of the sac on the left side, led to the discovery of the true state of affairs. Operation was first done for the condition on the left side, and here the hydronephrosis was found to have been caused by a congenital displacement of the kidney, and it was determined to secure better urinary drainage by shifting the origin of the ureter to the lowest point of the renal pelvis. This was accomplished by shortening the blind pouch by making a longitudinal incision and then suturing it in a horizontal direction. The procedure failed, however, in producing any more perfect drainage, and a few days later renal puncture was resorted to in order to relieve the symptoms. Soon after infection of the left kidney took place, which was then communicated to the right. Every known method was tried in attempting to relieve the patient and restore the normal passage between kidney and bladder, but without success. It was then decided to secure this end without the medium of the ureter, and a fistulous communication was devised between the bladder and the pelvis of the kidneys with the aid of a system of tubes, similar to what had been done in another patient with a solitary renal fistula (described in *Deutsche medizinische Wochenschrift*, 1903, No. 1). The appliance had been in good working order for over a year and the boy is in good general health. Twice a week the tubes are changed and the bladder and pelvis irrigated with boric acid solution. Notwithstanding the success of this procedure, the author still hopes to arrive at the same result by doing a resection of the ureter and implanting the same in the most dependent portion of the renal pelvis, which after the obstructions have been removed can be made smaller and will remain thus.

Berliner klinische Wochenschrift, June 13, 1904.

Gonorrhœal Stomatitis in Adults.—Jurgens believes that this process not only has a distinctive etiology, but also presents a distinct clinical picture. The patient, in the case which is reported, shortly after the appearance of a gonorrhœal urethritis, developed a diffuse inflammation of the mucous membranes of the gums and the cheeks. These were covered with a dirty gray membrane, which could be readily wiped away, but there was ulceration. In smear preparations the gonococcus was identified with difficulty, but better success was had with cultural tests.

Münchener medizinische Wochenschrift, June 14, 1904.

Operations Conducted Alternately by Daylight and the X-rays.—Grasey has devised an apparatus by which it is possible to operate with both of these sources of light as when looking for a foreign body imbedded in the tissues, such as a needle. The apparatus is so constructed that one eye of the operator may be employed in looking at the *x*-ray picture, while the other is engaged in following the steps in the operation on the part under treatment. The principle involved is like that in a camera lucida such as may be attached to a microscope for drawing purposes.

A Case of Trypanosome Disease in Man.—Gunther and Weber report a case of this tropical disease, which is apparently the first observed on the continent of Europe. The patient had been in South Africa and returned to Europe, where he became afflicted with what at first thought to be malaria. The main points in the history, which is reported in great detail, are as follows: the chronic course of the complaint extending over two years, recurrent irregular attacks of fever, loss of strength and decrease in the hæmoglobin, localized transitory œdemas, peculiar erythematous eruptions, enlargement of spleen and liver, which was more marked during the acute exacerbations, slow pulse and occasional dyspnœa, combined with abnormal irritability of the circulatory system. In addition there appeared an inflammatory process on the leg resembling the early stages of a phlegmon. As in the other cases reported, it was possible to demonstrate the presence of the trypanosomes in the blood during the attacks of fever. A further communication is promised on the results of treatment given.

Diagnosis of Typhoid Fever.—Rolly reports on the results of his observations with Schottmüller's method, by which the typhoid bacilli can be demonstrated in the patient's blood. By the aid of a syringe, 20 c.c. of blood are abstracted from one of the arm veins and mixed with glycerin agar at a temperature of 42° to 45° C. This is poured out in Petri dishes placed in an incubator for one or two days, and then examined. In fifty cases of typhoid subjected to this test cultures of the specific bacillus were obtained in 44; *i.e.* in 88 per cent. The number of colonies varies within wide limits, but it seemed that the larger numbers were associated with the early stages and the height of the disease. In sixteen cases it was found that during the early days of the disease the agglutination tests were negative, while the bacilli could be demonstrated in the blood, and as doubts of the true conditions usually exist during the first day such a method of diagnosis ought to prove of exceptional value. In general practice it is somewhat difficult to carry out this procedure and the writer proposes certain modifications. As it is necessary to keep the blood fluid, he advises mixing the blood as soon as it is ab-

stracted with 20 c.c. of a solution made up of peptone 5 gm.; grape sugar, 50 gm., in 100 c.c. of water. This is boiled from five to ten minutes. Blood to which this solution has been added remains fluid for a day, and can, therefore, be transported to a place where the proper laboratory facilities are obtainable. It was also sought to improve on the agglutination tests by substituting for the cultures of living bacilli a fluid in which the dead bacilli could be held in suspension. This was accomplished by killing the typhoid bacilli in a bouillon culture with formol. Experiment showed that agglutination takes place in the same dilutions, with the bouillon containing the dead, as that containing the living bacilli. Blood serum which failed to agglutinate the one also failed in the case of the other. In the case of the dead culture, agglutination takes place about fifteen to thirty minutes later, but is evident on either micro- or macroscopical examination. The bouillon containing the dead bacilli may be kept for considerable periods and still retain its efficiency.

French and Italian Journals.

Influence of the Soil on the Virulence of the Vibrio of Cholera.—A. Paladino-Blandini made cultures of the vibrio of cholera in dry earth, in moist earth free from organic matter, and in earth that was impregnated with fecal matter. In dry earth the virulence was decreased; in moist earth it was less rapidly diminished; in earth impregnated with a considerable amount of organic matter its virulence was increased. But if between two periods of remaining in the earth it passed through the body of an animal, its virulence was very markedly increased. Both its presence in the earth and in the animal were important factors in the increase of virulence. There seems to be a coincidence between the presence of the vibrio in the deepest levels of the subterreanean water, where the sun does not reach, and the coming of a severe epidemic of cholera.—*Giornale Internationale delle Scienze Mediche*, May 15, 1904.

Chorea in Pregnancy.—Vallois reports the case of a woman of twenty-six years, a primipara, who toward the end of the eighth month began to exhibit slight arrhythmical movements in the arms, and certain psychic disturbances. These movements increased till the whole body was involved. The child was born, but the cerebral troubles persisted. The patient had auditory hallucinations, and thought she heard voices calling her name. There was anæsthesia of the conjunctiva and of the pharynx, but no cutaneous anæsthesia. Then the choreic movements began to disappear, and instead of the phenomena of excitement, those of depression succeeded. The patient was badly nourished and became emaciated. Since labor there had been no rise of temperature. The pulse, which remained for a long time 104 to 112, rose finally to 132. The mental troubles grew worse, and the patient was sent to an asylum. This case is like most of its kind. The chorea is of an hysterical nature and not rheumatic.—*La Médecine Moderne*, June 8, 1904.

Laryngeal Syphilis.—A. Chauffard and Paul Viollet discuss this subject and present the history of several patients. They call attention to the predominance of nocturnal symptoms. A chill often ushers in the acute phenomena of syphilis. It is sometimes very difficult to differentiate syphilitic laryngitis from cancer, sarcoma, lupus of the larynx, and laryngeal tuberculosis. Ordinarily syphilitic infiltrations are indolent, while the ulcerations have a relatively rapid evolution. Cancer has a tendency to vegetate first, it is complicated with adenitis and its evolution is in general far more slow. In lupus there is generally noted the process of spontaneous cicatrization side by side with active lesions. The evolution of these lesions is still slower than in the case of laryngeal tuberculosis. The latter often presents the manipulations of acute or chronic œdema which are seldom seen in syphilis. The epiglottis is often attacked by the latter, while the arytenoids, especially, are attacked in tuberculosis. Finally, syphilis is not accompanied by concomitant pulmonary symptoms. The possible combination of syphilis with cancer or tuberculosis must be remembered. Syphilitic lesions capable of affecting the larynx and of giving the laryngoscopical image of paralysis are very varied. In order to establish a diagnosis of syphilitic laryngeal affections, a general examination of the patient must be made including an exploration of the ganglia of the neck, the lungs, the aorta, the thorax and its contents, the reflexes and the entire nervous system. Lumbar puncture is sometimes helpful in cases of suspected tabes. Laryngoscopical examination is most important.—*Gazette des Hôpitaux Civils et Militaires*, June 9, 1904.

Annals of Surgery, June, 1904.

Sarcoma of the Tongue.—C. B. Keenan finds only about three dozen cases of this nature on record. He adds one personal case. The patient was unwilling to undergo a radical operation though various portions of the tumor, in fact, almost all of it, was removed. He died some months later from recurrence in the abdomen, but examination at this time showed no signs of recurrence in the tongue. The author then gives a synopsis of the recorded cases. Analysis shows that they were all of the round-celled variety. The majority of them occurred between the fortieth and fiftieth year. Extensive metastases were the rule. Generally the growth was slow. They are distinguished from cancerous growths by the fact that the epithelium usually remains intact or ulcerates only after a long period. From gummata they are distinguished by the therapeutic test. Under the microscope, however, it is not always easy to distinguish a gumma from small-celled sarcoma. Wide excision is the only rational therapy.

Revival of Suprapubic Prostatectomy.—The object of the article of F. D. Gray is to call attention to the views of Freyer, whose work the author has been able to follow by personal observation. Freyer contends that a certain class of enlarged prostates, notably the large œdematous type, which he considers more common than do other authorities, can most safely and easily be reached by the suprapubic route with perfect restoration of bladder function and with a very small mortality. His method is one of enucleation through the upper route. His procedure is based on the work of Sir Henry Thompson, who taught that the prostate has a thin, closely adherent, fibrous covering, dipping between the lobes of the gland, and from which it cannot be enucleated; also that outside this capsule is another covering (which Freyer terms the sheath), in reality the layers of the rectovesical fascia, between which and the capsule is a natural "line of cleavage." Freyer's comparison of the prostate capsule, and sheath to an orange, with its closely adherent inner skin which dips between the various sections and is surrounded by the rind, from which it is readily enucleated, most perfectly conveys the anatomical idea on which his suprapubic enucleation is based. He calls attention to the fact that in fetal life the prostate is double—two lateral halves—and that later they are only united by the upper and lower borders, thus enclosing the urethra, while in the advanced adenomatous enlargement these connections, especially the upper, easily give way, facilitating their separation from the urethra.

Extensive Subcutaneous Laceration of the Abdominal Muscles.—D. N. Eisendrath reports the case of a man of fifty years who, while intoxicated, was caught between two street cars passing in opposite directions. He was admitted to hospital and presented a swelling about the size of an orange at the middle of the right iliac crest and extending somewhat below it. From the fact that this tumor was distinctly tympanitic on percussion and could be made to disappear into the abdominal cavity with a gurgle, he made the diagnosis of a traumatic hernia through the triangle of Petit. There were several other minor injuries. Operation was done sixteen hours after admission to hospital. Incision over the site of the iliac swelling showed that only the skin separated the peritoneal cavity from the external world. All of the muscles attached to the crest of the ilium (external and internal oblique, and transversalis muscles), as well as the transversalis fascia and peritoneum, were torn loose from their attachments. The skin incision was enlarged in both anterior and posterior directions, and the flaps retracted. It was then found that the injury was far more extensive than at first supposed. From the quadratus lumborum posteriorly to the middle of Poupart's ligament in front every structure which is normally attached to the crest of the ilium and outer half of Poupart's had been torn from its attachments. The lower edges of the muscles were irregularly torn and contused. The general peritoneal cavity had already been partly walled off by adhesions between the ascending colon (which had been displaced inward) and the anterior abdominal wall. In the iliac fossa were many loose pieces of omentum. The ascending colon was contused and dilated. By means of fourteen kangaroo tendon sutures the muscles were drawn down to the gluteal fascia and the defect closed. From the anterior superior spine of the ilium to the middle of Poupart's ligament, mattress sutures of kangaroo tendon were passed in a similar manner through the muscles *en masse*, and these then anchored by passing the two ends of the suture through Poupart's ligament itself, similar to the formation of the posterior wall of the inguinal canal in the Bassini operation. Small gauze drains were inserted at each end of the long skin incision. These were removed after forty-eight hours. Primary union occurred and the patient made a slow, though complete recovery.

Book Reviews.

La Séparation de l'Urine des Deux Reins. Par Georges Luys, Assistant du Service des Voies Urinaires à l'Hôpital Lariboisière. Préface par Henri Hartmann, Professor Agrégé à la Faculté, Chirurgien de l'Hôpital Lariboisière, Paris: Masson et Cie., 1904.

Renal surgery is a subject to which a vast amount of study is being devoted at the present day and, apart from the surgical treatment of Bright's disease, no branch of this department is of greater interest than that of diagnosis by examination of the urine obtained from each kidney separately. Among the methods of obtaining the urine of one kidney unmixed with that secreted by the other, that of Luys stands out most prominently.

In the present work the author, after showing the necessity of this means of diagnosis, reviews and explains the different methods (ureteral catheterism, compression of the ureter, and intravesical separation), and then treats of his own device, dwelling on the history of its invention, its construction, method of employment, action, and indications. Excellent results are shown in the reports of personal cases, 210 in number, in which the separator has been used on patients of both sexes and all ages, and with every imaginable disease of the kidneys. Many of these reports are illustrated with well-executed pictures of the kidneys removed after diagnosis by Luys' method. The author has not been precipitate in the recording of his cases, but has waited three years and has demonstrated the value of his invention over two hundred times—an experience which gives him the right to speak with authority.

The book is a timely one, and will be consulted with profit by all who are interested in renal pathology.

Theorie und Praxis der Augengläser. Von Dr. E H. Oppenheimer, Augenarzt in Berlin. Mit 181 Textabbildungen. Berlin: August Hirschwald, 1904.

The volume is one of 200 pages, and is principally devoted to the description of the various kinds of eye-glasses and spectacles and the theory and art of their construction. In the first chapter a short history of eye-glasses dating back to 1800 B. C. is found. The volume of production of spectacle lenses at the present time is mentioned. The second chapter describes the manufacture of the ordinary forms of eye-glasses; the third, spectacles. Chapter X is devoted to a description of the proper way of adjusting glasses to the face. Chapter XI describes in detail the various kinds of glass employed in the manufacture of eye-glasses. Chapter XIII treats of the various ways of numbering glasses.

The book is well illustrated. It is calculated to acquaint ophthalmologists with what is being done in the art of making eye-glasses, and this purpose it accomplishes in a very excellent manner.

A System of Practical Surgery. By Drs. v. Bergmann, Berlin, v. Bruns, Tubingen, and v. Mikulicz, Breslau. Edited by Wm. T. Bull, M.D. Vol. II, Surgery of the Neck, Thorax, and Spinal Column. New York and Philadelphia: Lea Brothers & Co, 1904.

The second volume of this work closely follows the appearance of the first, and the remaining three volumes of the series are scheduled to come out in rapid succession. It includes the surgery of the neck, thorax, and spinal cord, and in the list of contributors are the names of v. Angerer, v. Bruns, Erhard, v. Eiselberg, Henle, Hofmeister, Jordan, Kümmell, and Riedinger. Their names are not in all cases, however, appended to the chapters in the book for which they are responsible, in some respects an unfortunate omission. The following topics are considered: Malformations, injuries, and diseases of the neck, the larynx and trachea, thyroid gland, thorax and its contents, the mammary gland, the spinal cord, and the vertebral column. In the latter chapter the subject of tuberculous spinal ostitis is considered, as regards diagnosis and treatment, quite as fully as in some special textbooks on the subject. In this, as well as in other parts, one is impressed by the evident desire to make the work practical; more space being given to diagnosis and treatment than to etiology or pathology, except when one has a bearing on the other. The typographical work is up to the high standard to be found in most American medical books, and the illustrations are numerous.

An Introduction to Vertebrate Embryology, based on the study of the frog and the chick. By Albert Moore Reese, Ph.D. (Johns Hopkins), Associate Professor of Histology in Syracuse University and Lecturer on Histology and Embryology in the College of Medicine. New York: G. P. Putnam's Sons, 1904.

This volume contains 291 pages and 84 illustrations. It is, the author tells us, the result of a need for a textbook on the embryology of the chick and frog, at once concise and convenient. The volume is intended as an outline from which the instructor can expand as he sees fit. The needs of the medical student have been largely considered, and very little space has been devoted to theoretical discussions. The treatment of the subject is convenient for the student, the development being described day by day (for the chick, for example, daily up to the sixth day), instead of organ by organ. The text is clear and easily followed, and devoid of unnecessary technicality; and the illustrations are well selected. All in all, this little volume forms a convenient manual for the student.

The Therapeutics of Mineral Springs and Climates. By I. Burney Yeo, M.D., F.R.C.P., Emeritus Professor of Medicine in King's College, London, etc. Chicago: W. T. Keener & Co., 1904.

Dr. Yeo has become well-known to the profession on this side of the Atlantic through his excellent "Manual of Medical Treatment," and his attractive monograph on "Food in Health and Disease." The present volume may also be classed as a useful work of reference. Part I (456 pages), comprising about two-thirds of the book, treats of mineral springs and contains chapters on the nature and composition of mineral waters, their action and modes of application, with the various accessory methods employed in the internal and external use of waters, together with a description of the principal European springs, arranged in alphabetical order. As no geographical limitation is expressed in the title, it would not have been out of order, nor would it have been prejudicial to the practical value of the work, to have included some of the American springs, many of which will take rank with the best of those found in Europe. Part II relates to the subject of climate, and contains an account of the several varieties of climates with a brief description of the various British and Continental winter and summer resorts, the therapeutics of sea voyages, the uses of sanatoria, etc. In this part of the book the author far transcends the geographical limits allotted to mineral springs and takes his readers as far afield as South Africa and the Pacific Coast of the United States. It is gratifying to observe that while Dr. Yeo is an ardent advocate of the modern sanatorium treatment of tuberculosis, he is by no means to be classed with the latter-day group of extremists who taboo the subject of climate as being quite negligible in the management of this disease. We think no one can read the excellent chapter on climatic therapeutics without being impressed by the forceful logic of the author's views.

The Complete Medical Pocket-Formulary and Physician's Vade-Mecum. Containing upward of 2,500 prescriptions, collected from the practice of physicians and surgeons of experience, American and foreign, arranged for ready reference under an alphabetical list of diseases. Also a special list of new Drugs, with their Dosage, Solubilities, and Therapeutical Applications, together with a table of Formulæ for Suppositories; a table of Formulæ for Hypodermic Medication; a list of drugs for Inhalation; a table of Poisons, with their Antidotes; a Posological table, a list of Incompatibles; a table of Metric Equivalents; a brief account of External Antipyretics, Disinfectants, Medical Thermometry, the Urinary Tests; and much other useful information. Collated for the use of Practitioners by J. C. Wilson, M.D., Physician to the German Hospital, Philadelphia, etc. Third Revised Edition, Philadelphia: J. B. Lippincott Co., 1904.

Being alphabetically arranged, this presents a handy reference book. There are nearly 2,600 formulæ. Why they should be numbered does not appear. The "list of authorities" seems superfluous.—The lists of new remedies, poisons, measures, etc., are good.

Immune Sera: Hæmolysins, Cytotoxins, and Precipitins. By Prof. A. Wassermann, M.D., University of Berlin. Authorized Translation by Charles Bolduan, M.D. New York: John Wiley & Sons; London: Chapman & Hall, Limited, 1904.

The subject of serum diagnosis and therapy, already grown to considerable proportions, is constantly increasing in importance. The lack in our language of any simple and concise exposition of the subject has led Dr. Bolduan, as he tells us in his preface, to make this excellent treatise of Prof. A. Wassermann more readily accessible to the English-reading medical public. For this the thanks of many are due him, for the subject is presented by the author in a way which leaves little to be desired by the seeker after information who has not the time or the opportunity to study at first hand and in large treatises the details of this difficult science. Any one, by one or two careful readings of this little book of 76 pages, can familiarize himself with the whole theory of immunity, as it is at present held, and so be in a position to understand much in modern medical literature that else must be to him a sealed book.

Society Reports.

AMERICAN SURGICAL ASSOCIATION.

Twenty-Fifth Annual Meeting, Held in St. Louis, June 14, 15, 16, and 17, 1904.

The association met in the Assembly Hall of the Board of Education, under the Presidency of Dr. N. P. Dandridge of Cincinnati, Ohio.

President's Address.—Dr. N. P. Dandridge departed somewhat from the practice of his predecessors, and instead of bringing before the association some medical topic based on his own work, or attempting a discussion of some subject of active interest, he took the members to the back woods, and interested them in the life and exploits of a pioneer doctor. He depicted a man of high scientific attainments and true culture, with all the elements of character which become the doctor and the man. He gave an exhaustive sketch of Antoine Francois Saugrain de Vigni, who was born in Paris, February 17, 1763. He came from a long line of librarians, booksellers, and printers, who, as far back as Charles IX in Lyons, and Henry of Navarre, had served the Royal family in France. His knowledge of mineralogy made his advice often called for in the development of the mines in the Ohio Valley. In the wilderness he supplied himself with ink from a natural Chalybeate water and an infusion of white oak bark, and when in need of a fire, lighted it from a lens made by two water crystals with clear water between. Dr. Saugrain gave notice of the first vaccine matter brought to St. Louis, and indigent persons were vaccinated gratuitously. He practised in St. Louis till his death, in 1820. He must have been eminently successful, for he left a large landed estate for the support of his wife and six children. His scientific work lives in tradition, and has gained for him the title of the "First Scientist of the Mississippi Valley."

What Are the Minimum Requirements for Aseptic Surgical Operations in Hospitals Where the Surgeon Is Assisted by a Large Staff of Internes and by Nurses from a Training School?—This subject was discussed with great detail by Dr. Geo. H. Monks of Boston, Mass.

Minimum Requirements for Aseptic Operations in a Hospital in Which the Personnel of the Operating-room Is Permanent.—Dr. A. J. Ochsner of Chicago, in a paper on this subject, pointed out the fact that with a permanent personnel a definite system could be developed, which was most satisfactory, because the observations which suggested changes as well as those which confirmed satisfactory methods could be carried through a large continuous series of cases under unchanged external conditions. Stress was laid upon the importance of simplicity in the methods chosen. The less that was done in any given case, the slighter was the likelihood of doing harmful things. There should be uniformity in carrying out a plan of work in order that everyone connected with the system might know what had been done and what was to be done by the other members of the personnel in any given case. Above all things, the methods should be reasonable in their details. This would make the work more attractive, and consequently more satisfactory to those engaged in its prosecution. The author then gave a detailed account of the system followed by him and his assistants at the Augustana Hospital, where he had had an opportunity to develop uniform methods with permanent conditions during a period of fifteen years. The system comprised disinfection of patient, operator, assistants' and nurses' hands, instruments, silk, silkworm gut, horsehair, drainage tubes, hand brushes, dressings, implements, towels, sheets, etc. Stress was laid particularly upon the danger arising from tying sutures too tightly, thus causing pressure necrosis, which favored the development of micro-organisms accidentally introduced. The method of selecting assistants and nurses was described, and a table illustrating the manner in which each assistant recorded the progress of the wounds under his care was appended.

Dr. Charles Harrington of Boston, Mass., read a paper, by invitation, in which he detailed his studies in asepsis.

Dr. De Forest Willard of Philadelphia said that surgeons who had to deal with the practical side of asepsis in surgical operations knew that their results satisfied them to a certain degree, but it must be confessed that they had failures, and it was very essential to know whether the failures were due to the method or methods employed, or whether there were difficulties which could not be overcome. Difficulties would beset surgeons, but the question resolved itself largely into one of extreme care on the part of everyone, from the surgeon down to the lowest assistant, who had the materials in charge or in preparation. There could be no doubt that a hospital which had permanent assistants, permanent nurses, was the one that was likely to secure the best results from operative procedures on the patients under its care.

Dr. Charles B. Nancrede of Ann Arbor, Mich., emphasized the two important points, one of which was inhibition, and the other, tissue resistance. A germ might be inhibited to the point that would render it safe in a given wound.

Dr. John E. Owens of Chicago stated that different results were reported by different surgeons after using the same methods, and he had often wondered whether some of them might not have been due largely to the habits of surgeons. So far as the disinfection of hands was concerned, a few years ago he was compelled to stop the use of corrosive sublimate on account of the condition of his hands, and since then he had been scrubbing them thoroughly with soap and water, keeping the nails of the fingers pared down, and afterward washing the hands with salt solution and alcohol, and he thought his results were as good in hospital work as where other chemicals for sterilization were used.

Dr. W. W. Keen of Philadelphia spoke of his own method and the results which he had obtained by some experiments. He had adopted for several years past for the cleansing of his hands, a method which was first directed to the attention of the profession by Weir, namely, the use of chloride of lime and carbonate of soda. The hands were washed thoroughly with soap and water, and in order to do this he had in his own private hospital and at the clinic at Jefferson, little egg boilers, which were practically hour-glasses or sand-glasses that were reversible. These were marked "soft-boiled, well done, and hard boiled." Soft boiled corresponded to about three minutes; well done, five minutes, and hard boiled, seven minutes. He told his assistants that when they had scrubbed their hands until the sand had reached "well done," good and faithful servant, they should stop. Every person, who took an active part in his clinic, had a culture taken from under the thumb, or one or two finger nails, particularly at the root of the nail, and from the free surface of the skin. During the last winter there were 213 cultures made, from the hands of himself and his assistants in the clinic at Jefferson. Of this number there were only three cases in which any culture was obtained. This made practically a sterility of 9 per cent., and an infection of about 3 per cent. There was but one person who was free at every clinic, and that was the head nurse, who was a permanent official in the operating room. All the other nurses, and all the assistants, except this principal assistant, changed every three months. He thought the method of keeping such a record of every person's hands served an admirable purpose by creating a sort of rivalry among those who were endeavoring to have clean hands before operation, and it was more to prophylaxis in preventing infection than in the results obtained, he attributed the value of the method.

Dr. W. B. Coley of New York did not believe sufficient stress had been laid upon sterilization of the skin,

and although some authorities maintained it could be done properly in a few moments before operation, his experiments showed that with careful preparation the day before operation, in addition to what was done on the day of operation, sterilization of the skin even then could not be said to be perfect. In 250 cases in which he had examined portions of the skin or Reverdin grafts, taken from the field of operation immediately before, 25, or 9 per cent. of the cases, showed all kinds of cultures, some of them being staphylococcus and streptococcus. The only case of suppuration in two hundred cases showed a pure culture of the streptococcus. Carefully sterilizing the hands, using tincture of green soap, applied carefully, brushing and hot water, then washing thoroughly with 95 per cent alcohol, with the use of rubber gloves, would give as good results as any of the measures which render the hands very hard. With reference to primary union, an important element in aseptic surgery was to guard against the bruising of tissues.

A Clinical Review of Forty-six Operative Cases of Duodenal Ulcer.—This was the title of a joint paper by Dr. Christopher Graham and Dr. Wm. J. Mayo of Rochester, Minn. The authors stated that a careful history was of prime importance. The leading symptoms in the forty-six cases reported were, first, pain, which might be due to peritonitis, distention from gas formation, pyloric spasm, and the irritation of acid gastric contents on open ulcer. The pain might come on in colics or last for some hours. Second, vomiting, principally of sour, bitter liquids, or if obstruction supervened of food after varying intervals. Third, gastric insufficiency from interference with drainage, There was usually hyperacidity of gastric contents, constipation, and a great desire for food, although the patient reduced the diet, and ate often a small quantity, but might fail to get the relief sometimes obtained in gastric ulcer proper. In latent cases, evidences of blood in the fecal movements might be the only sign. Differential diagnosis from pyloric ulcer in some cases might be impossible. A considerable number of cases closely resembled gallstone disease, and differentiation often could not be made. Such an error in diagnosis did not militate against the clinician, as both conditions were purely surgical and the differentiation in many cases must be made on the operating table. During the past eighteen months, 27 per cent. of their operative gastric and duodenal ulcers involved the duodenum in combination—53.33 per cent. There were 33 males, and 13 females; in 43 out of 46 cases the ulcer was easily detected upon abdominal exploration as a thick, white, scar-like area. Liability of duodenal ulcer to perforate was greater than gastric, but more often safely protected by adhesions. Relatively, sterile contents was also favorable. In all cases the ulcer was situated in the first two and one-half inches below the pylorus, and entirely above the entrance of the common duct of liver and pancreas, with its alkaline secretion, showing the effect of the gastric juices on the duodenal wall. In all doubtful cases of differentiation, between duodenal ulcer, pyloric ulcer, and gallstones, the authors recommended making an incision through the right rectus muscle, one inch to the right of the median line. Gastroenterostomy best met the indications, in that it diverted the gastric contents. In acute perforation, suture was recommended, with suprapubic drainage, with after-treatment, and exaggerated Fowler's position, sitting posture. The 46 cases were divided into five groups: (1) Acute perforation of chronic ulcer, 4 cases, 2 deaths. (2) Acute hemorrhage in chronic ulcer, 1 case, one death. (3) Duodenal ulcer with gastric complications, 25 cases, one death. (4) Duodenal ulcer, with gall-bladder and liver complications, usually due to adhesions from chronic peritonitis, 9 cases, one re-operation, no deaths. (5) Eight cases, chronic pain and distress with debility, no deaths. Total, 47 operations, 46 cases. Five operations for acute conditions, with three deaths; 42 operations for chronic conditions, with one death.

Dr. E. Wyllys Andrews of Chicago had seen in the last year or two several cases in which a marked hyperplasia, patches of exudate, with thickening of the wall of the duodenum, ulceration of the first inch and a half of the duodenum connected with a similar condition of the pylorus, had produced such a degree of massive thickening that clinically, at the time of operation, it was indistinguishable from carcinoma. In one such case the operation, which was a McGraw elastic ligature gastro-enterostomy, left him in a dissatisfied state of mind, as he feared he should have done a more radical extirpation, and yet, in this particular case, it was his fortune to do a second operation for obstruction a year after the first operation, and he found, very much to his surprise, absolute disappearance of the thickened massive wall, which had formed in the first place and simulated carcinoma. This was what Mayo himself called attention to, namely, when the obstruction was relieved, when the flow was permitted from some other point, the inflammation, or ulceration, at any rate, the hyperplasia disappeared at the point of irritation, and secondary to this again, when obstruction had been relieved by drainage below, the drainage below ceased to act, and again the opening became closed, so that the surgeon had to do sometimes a secondary gastroenterostomy.

Dr. John B. Murphy of Chicago said the practical lesson the paper taught was the frequency of occurrence of duodenal ulcer; that it was not recognized, and that it was not differentiated from gastric ulcer or gall-bladder disease, whether it was of infective or of stone origin.

Dr. Alexander Hugh Ferguson of Chicago asked Dr. Mayo if he had outlined for himself the class of cases in which he would do a posterior gastroenterostomy: also the class of cases in which he would do gastrojejunostomy or Finney's operation. The speaker mentioned one case in which he did a pylorectomy, removing the end of the pylorus, and a portion of the duodenum, with an excellent result.

Dr. Mayo, in closing the discussion, and in replying to the remarks of Dr. Ferguson, said he did not know that they had ever tried to excise any of these ulcers excepting in connection with Finney's operation. They were irregular and thick; they led to large vessels, close to the common duct, and it was difficult to get a good stump. He thought the best thing to do was to make a gastro-enterostomy, which would afford, at least, temporary relief, but the gastroenterostomy opening was very likely to contract, so that food would after a time continue to pass down over the duodenal ulcerated surface, and sometimes these patients would return for a second operation.

Complete Removal of the Shaft of the Tibia, with Restoration of the Bone.—Dr. George Ben Johnson of Richmond, Va., detailed seven cases of this operation.

Dr. De Forest Willard said it was greatly to be regretted that not only the family physician, but many surgeons, treated such cases as Dr. Johnston had reported for rheumatism, when there was really no sign of that disease, and they were, from the beginning, cases of acute suppurative osteomyelitis. Then came the septic symptoms. The physician treated them for typhoid fever and other conditions, until they drifted into the hands of surgeons, with bones absolutely destroyed, the majority of them crippled for life, with deformity of the legs. These cases from their incipiency were virulent in type, and the only time for treatment was forty-eight hours after the onset, and the quicker the surgeon got inside the bone, the better. If cases of appendicitis demanded early operation, surely it was doubly important that cases of acute osteomyelitis should be diagnosed and operated early.

Dr. A. J. Ochsner stated that in a large porportion of cases in which the shaft of the bone was entirely loose,

when the periosteum was incised, if the bone was left in place, there would be a regeneration of a considerable portion of the apparently dead bone. If one took such cases as had been described, made an incision which extended from one end of the bone to the other, split the entire periosteum, made it necessary for the flow of lymph to be away from the tissues, left bone there as a bone graft, he had found in a considerable number of cases that there would be a regeneration of a large portion of this bone.

Dr. John Collins Warren of Boston said the subject was one that should be thoroughly discussed, and a message given to the profession to realize the importance of this septic process, so that cases of acute osteomyelitis might be sent to surgeons early and treated properly. As to treatment, the great point was to prevent the spread of sepsis. This might be accomplished by trephining the bone, by proper disinfection, by a comparatively moderate operation, or, it might be necessary in certain cases to do quite a radical operation.

Dr. P. S. Conner of Cincinnati, Ohio, said that in some of these cases the disease originated superficially. The cases were uniformly mistaken for erysipelas. The redness of the overlying skin was taken as an indication of the existence of the disease. Then, we had a condition simulating typhoid fever after the disease had existed for a considerable length of time, or rheumatism for a while, then typhoid fever, when the condition did not subside. Early boring of the lower end of the tibia would put a stop to the trouble. A moderate incision would not infrequently end the trouble if boring did not.

Dr. S. H. Weeks of Portland, Me., said that while many of these cases began as a periostitis, requiring a simple incision down upon the bone, there were many others which commenced as an acute osteomyelitis in the medullary canal, and he believed under such circumstances when an incision was made down to the bone, there should be an opening made into the medullary canal, and that canal drained.

Unavoidable Post-operative Calamities in Abdominal Surgery.—Dr. Maurice H. Richardson of Boston read a paper with this title, which was based upon his experience more especially in abdominal surgery, and related exclusively to fatal cases. Four classes of calamities were considered: (1) Suppression of urine; (2) inexplicable deaths, with symptoms of local and general sepsis, but without any detectable bacterial source; (3) uncontrollable capillary hemorrhage; (4) pulmonary embolism. Suppression of urine could be regarded as an unavoidable accident only when it took place after the urine had been shown to be normal by the most searching study. The influence of ether alone in causing suppression after operations was not regarded as sufficient and sole cause of this calamity. It was doubtless true that failure of the kidneys properly to perform their functions was due to some pathological change in the secreting substance, if not a pathological change, a tendency to glomerular irritation or real inflammation, but a change or tendency which could not be detected beforehand. Such suppression of urine, however, might be prevented by the avoidance of all but imperative operations whenever there was the least evidence of renal disease, especially an insufficiency in the elimination of urea. Renal suppression was not believed by the writer to be the result of etherization alone. In certain very rare instances death had taken place after abdominal operations without any pathological cause whatever. In one illustrative case, after an aseptic, though difficult and bloody operation, the patient presented the typical clinical picture of fatal general peritonitis. The pathologist at the Massachusetts General Hospital could find no evidence whatever of bacterial infection at the autopsy or in the laboratory. That there was an infection the essayist had no doubt, but by a germ which produced none of the usual physical signs of sepsis, which failed to grow on ordinary media, and which was not stained by the ordinary media. Uncontrollable capillary oozing might be regarded as unavoidable, and beyond power of prediction only when it took place after careful examination of the blood with reference to its coagulability, and other possible evidences of a tendency to bleed. Capillary hemorrhage from jaundice might be in certain instances uncontrollable. It could be regarded as uncontrollable only when operation must be performed in spite of the evidence of the tendency to hemorrhage. The coagulation tumor did not reasonably assure safety against bleeding, even if it was shown experimentally to be brief. The author's last fatal hemorrhage in jaundice took place from the capillaries of the lesser curvature of the stomach, remote from the operation area, though the blood coagulation tumor was perfectly satisfactory. In another case a fatal and uncontrollable capillary ooze followed an operation upon the common duct after a year of biliary fistula. In this case no bile had entered the intestine during the existence of the biliary fistula. The most frequent of such rare calamities was sudden death from pulmonary embolism. The cause of death could be neither predicted nor prevented. It occurred with no peritonitis. The probability of embolism being the result of a phlebitis was considered. In the author's experience, in a considerable number of deaths there were no premonitory symptoms whatever, while in cases of phlebitis, definite and unmistakable, no such accident occurred. Pulmonary embolism had been observed most frequently after pelvic operations upon women with large uterine or ovarian tumors, and especially in women long exsanguinated by fibroids.

Papillary Cysts and Papillary Tumors of the Ovaries.—Dr. Samuel Pozzi of Paris, France, read a paper on this subject, in which he summarized as follows: (1) Papillary tumors of the ovary, cystic or solid, must not be considered as always malignant. Some of these tumors never undergo malignant degeneration, and do not relapse after removal. Some relapse after a long time, and locally without metastases. (2) A careful distinction must be made between carcinomatous generalization, which takes place through the lymphatics and blood-vessels, and simple grafts which result from contact, or from the growing over the peritoneum of detached papillary vegetations of the ovary. This process is benign and can be compared to the grafting of papillomas and warts of the skin. (3) Some of the tumors undergo a malignant degeneration which is for some time limited, but may later extend all over the mass, and which at last brings on a real generalization with cancer metastases. Before this last period, and at the outset of the malignant transformation, it is quite impossible to discern it with the naked eye, and microscopical investigations are needed. The prognosis is always uncertain in operations of this kind before a thorough pathological examination. Even such examination may lead to misinterpretation, if it has not been carried all over the tumor, for the degeneration may be limited to a small part of the growth. (4) When positive symptoms of malignancy are absent, such as cancerous cachexia or visceral metastases, operators must always treat these tumors as if they were benign, and proceed to remove, to the largest extent possible, the neoplasm. The disseminated growths, or even small parts of the papillary tumor detached and lost in the peritoneal cavity may disappear. In other cases they may be the origin of local recurrence. But these relapses can be treated successfully by secondary operations. (5) Frequency of successive invasion of both ovaries by papillary tumors, furnishes an indication to remove the adnexa on both sides, even if one is still healthy, at least in women who are near the change of life. In young women it would be better to preserve a non-diseased ovary. (6) In bilateral papillary tumors the operative technique can be greatly improved by performing partial or total hysterectomy, according to the case. (7) Drainage is not necessary when the cysts

have no outside vegetations, and when there is no ascites. But in case ascites exists for some time, it would be well to drain the peritoneal cavity. Incomplete removal, or even an exploratory section, in unoperable cases, is often accompanied by a real diminution of ascites, with local and general improvement."

Ankylosis Treated by Arthroplasty.—Dr. John B. Murphy of Chicago spoke on this subject. He mentioned three types of ankylosis, namely, ankylosis from periarthritis; ankylosis from capsular lesions, and bony ankylosis. Bony ankylosis could be relieved. Tissue could be interposed to prevent reëstablishment of bony union, and with the recognition of the changes which occurred in fat close to the aponeurosis, a joint could be produced with a serous-secreting surface. His experimental work had shown that after the removal of the hip-joint in a dog, cartilage, synovial membrane, and the articular surfaces in their entirety, with replacement of tissue in the acetabulum, and replacement of bone again, he had produced a typical synovial membrane in the sense of a hygroma. In the production of hygroma pressure on fatty tissue had a tendency to bring about a coalescence of the small fatty capsules. The shaft of these capsules produced a serous secretion, and there was developed a condition which was seen in housemaid's knee, over the trochanter of the boilermaker, and over the wrist of the stonecutter. A serous-secreting surface was brought about. This could be done in a joint. The surgeon could restore joints to practically their normal condition. The first case he reported was one of bullet wound of the abdomen. The bullet passed through the abdomen a little to the right of the median line, passed across the abdomen, perforated the intestine eight times, fractured the head of the femur, lodged in a pocket, remained there, worked its way out through ulceration, and was finally voided through the intestine. The wounds in the intestine were sewed up, and the patient recovered, with a sinus. The speaker saw the patient with ankylosis of the leg at right angles. He passed around a skiagraph which showed bony union. After removing the head of the femur transperitoneally, curetting and removing the bony débris from the ilium, the wound was allowed to heal, and a plan was devised for the restoration of the joint and the relief of deformity. He decided that it was necessary, first, to expose the joint and to secure bony tissue for the new head. Second, it was necessary to interpose between the fragments not only muscle, but fascia, covered with fatty tissue, because the fatty tissue here, subject to pressure, like the fascia lata of the trochanter, formed hygromata. A U-shaped flap was made, carrying with it fascia lata and all the superficial tissue and skin, then the joint sawed from around the trochanter major. None of the muscles was divided. A circular chisel was used to chisel out the bone in all directions, and with the assistance and leverage of the femur and chisel a fracture was produced at the base of the cavity, and the head, which was new bone formation, as the original head was removed, was thrown out in connection with the neck, rounded off with bone-cutting forceps, and curette used to enlarge the cavity. The next step of the operation was to separate the fascia lata with its fat and a few fibers of the gluteus muscle; a flap was swung in behind the muscular attachments, and the trochanter major put in around the head of the femur and sewed to the neck. The neck was made short to prevent reunion of the fibrous portion of the capsule which remained, because if the capsule remained in its fixed position, the ankylosis would continue, and this was one of the practical points he derived from this particular case. The trochanter major was sutured to the neck, the head replaced, the trochanter major rounded off, the flap turned down and the wound drained. The result of the operation was ideal. Dr. Murphy passed around a photograph showing the patient as he stood in the erect position, and the degree of flexion obtained at the end of four months after operation. The patient now had perfect motion and flexion. He mentioned other cases on which he had operated by this method, with gratifying results. The method was largely intended for the treatment of joints with ankylosis.

New Aids in Diagnosis of Surgical Diseases of the Kidney.—Dr. A. T. Cabot of Boston read a paper on this subject. His conclusion from the experience he had had and from his study of the work of others, were that segregation of the urines was of great use sometimes in deciding the question as to which kidney was diseased, or even as to which was most affected, Determination of the functional capacity of the kidney by testing the elimination through it might be of assistance by adding strength to what evidence we had, but would be often misleading if too implicitly relied upon for deciding operative measures.

Report of a Case of Acute Pancreatitis Associated with Gallstones.—Dr. James Bell of Montreal said that the demonstrated facts in his case were: (1) That in March, 1898, there were all the characteristic lesions, as well as the signs and symptoms of acute pancreatitis, and at the same time an apparently quite healthy liver and gall passage, with two or three stones in the gall-bladder. (2) That all signs and symptoms of pancreatitis disappeared, the patient recovering, and considering himself quite well until nearly two years later, when a new train of symptoms developed, which were characteristically those produced by gallstones. (3) Three years after the attack of acute pancreatitis it was demonstrated that while extensive and serious pathological changes had taken place in the gall-bladder and bile ducts, all local signs of acute pancreatitis had during the same period of time entirely disappeared (subperitoneal fat necrosis, and swelling of the pancreas); that was to say, that acute pancreatitis developed before there were any pathological changes in the gall-bladder and bile ducts, and that while such changes were taking place the pancreatitis was recovered from. These facts would seem to be at variance with modern views of the etiology of acute pancreatitis, which tended to attribute this condition in a general way to a pathological change in the common bile duct due to the passage of gallstones from the gall-bladder to the intestine.

The Treatment of Congenital Cleft Palate: A Plea for Operations in Early Infancy.—Dr. Truman W. Brophy of Chicago read a paper, by invitation, on this subject. After referring to the work of Lamonier, Kirmisson, Roux, and many others in this field, the essayist stated that after having studied carefully the literature and the methods pursued by other operators, he had endeavored to overcome the objections and to avoid the difficulties with which the older surgeons contended, and he was satisfied that the most desirable time to select for operating was within three months after birth. In operating at that time one was able to secure more satisfactory results than later in life, and avoided the objections usually raised by surgical writers. He believed in operating at as early an age as practicable after birth, preferably within three months, and his experience of twenty years in operations performed for the closure of cleft palate, at from ten days to fifty years of age, including 927 operations, had more and more justified the practice. Among the advantages mentioned in favor of early operations, were the following: Surgical shock was less because the nervous system of a young child was not well developed, and it was not, therefore, capable of receiving the same impressions that it would later in life. Furthermore, young children usually reacted better. All mental apprehensions were eliminated, and alarm and dread were among the most powerful factors in producing shock. Following early operations there was much less deformity, for all the tissues, bony as well as soft, developed naturally and according to accepted types. When the operation was

postponed for a few years, it was very difficult to secure as good results. When the operation was made in early infancy, the parts were sufficiently developed to give possibility for normal speech when the child had reached a speaking age. The author described his method of operating on cleft palate in detail, a description of which has heretofore been published in both dental and medical journals. In conclusion, the author stated that if operations were made later in life, the patient should be placed under the instruction of one who had the perseverance, the ability, and the patience to teach him how to overcome the defective speech which he had acquired.

The Evolution of Surgery.—Dr. J. Ewing Mears of Philadelphia read a scholarly paper with this title. He divided this unfolding of surgery into three periods of time. (1) That which extended from the beginning to the time of Ambroise Paré, 1517-1519; (2) the use by Johns Collins Warren (1846) of ether as an anæsthetic in surgical operations, and (3) the discovery and introduction into general use by Sir Joseph Lister (1860-1875) of the antiseptic treatment of wounds. Each period was taken up and considered in a masterly manner.

A Mechanical Device for Gastric and Intestinal Anastomosis.—Dr. F. B. Harrington of Boston described a ring for the purpose of intestinal anastomosis. The advantages of this ring were stated as follows: (1) Safety and speed. A complete resection and suture can be easily done in fifteen minutes, and with as great speed as by any more protracted method. (2) Cleanliness. Assisted by clamps, the purse-string sutures prevent even a mucous ooze, while the continuous stitch is being placed. (3) The intestinal suture is more easily done over the ring than without it. (4) It is safe to use a single layer of continuous stitches, since the ring allows a perfect approximation to be made, and afterward protects the suture until adhesions have formed. (5) The handle is very useful for holding the intestines in convenient positions for sutures. (6) It is not necessary to sew up any of the layers, since a study of specimens from animals and human beings shows that the mucous membrane will slough in any case, and that repair is more rapid when the mucous membrane is not sutured. (7) The presence of the ring guarantees a free opening at the site of operation. (8) In case the continuous stitch should be improperly applied, the weak spots are protected by the ring itself for at least three days, until the ring breaks down. This allows strong adhesions to form. (9) After operation the ring holds the suture immovable, and acts like a splint. The weights of the individual segments of the ring vary, as most other appliances of a similar nature.

Dr. J. W. Draper Maury of New York City, by invitation, stated that instead of using the elastic ligature at the Laboratory of Columbia University, they had been employing twine. The specimen which he exhibited was made with the elastic ligature put in by a square knot, thus differing from Dr. McGraw's technique; but for the last three months he had obtained as good results by using simple twine instead of the elastic ligature. The method of introducing the twine might follow the McGraw technique, although the triangular stitch possessed a very distinct advantage over it. This stitch punched out as much tissue as might have been included in the triangle. As to time, it would cut through in less than three and a half days. It must be very tightly tied. This was the sole requirement to success. Dr. Maury demonstrated on a chart the technique of introducing the triangular stitch, and stated that he included about one-third the circumference of the gut in the stitch. The gastric triangle should, as a rule, be made larger than the intestinal. He then passed around photographs of specimens made by this method, and a preparation from the gut of a pig, which demonstrated how free an anastomosis might be established. He also showed a number of circular bits of twine which had been used in executing the technique. They had cut the triangle out and had been recovered after their passage through the rectum.

The Subtle Force of Radium.—Dr. Robert Abbe of New York City narrated his experience with this new therapeutic agent, saying that radium had a powerful and seemingly beneficial effect upon cases of recurrent carcinoma. Cases were cited in point. He mentioned one case of virulent, typical carcinoma of the scirrhous type, in which the carcinomatous nodules were reduced to one-third their original size by radiomization. The agent had been used in cases of lupus, superficial epitheliomata, carcinoma, rodent ulcer, superficial sarcomas, etc. In cases of superficial recurrent carcinoma of the breast, if radium was applied to the diseased area for a considerable time, say an hour, then the patient permitted to go, and the agent reapplied at intervals of two or three days, the carcinomatous masses would melt away in some cases. In other instances, these masses would disappear under the use of the *x*-ray, still others would resist the action of the *x*-ray, while radium would act beneficially. Radium had an extraordinary power in inhibiting the growth of malignant cells in some cases.

Dr. W. W. Keen of Philadelphia said that one positive fact was worth a dozen negative ones. One could not get away from the facts presented by Dr. Abbé and others in regard to the use of radium. On the other hand, members of the profession ought to report their negative as well as positive results. He had had an experience now covering twenty-two cases in which radium was used. Whether his results were due to the quality of radium, to a difference in the character of the growths, to the method of using it, or what not, he did not know. But to sum up his experience, in not one single case had there been the slightest benefit, except in one feature, and that was as to pain. Unquestionably in cases of carcinoma, patients had suffered less and in a large number pain had disappeared. In one case of tic douloureux of the lower jaw the man left the hospital at the end of a month practically well. In the course of six or eight weeks the patient wrote him that he had had a recurrence of the pain. Dr. Keen wrote him to return for treatment, but had heard nothing from him since, and whether the pain had disappeared or not, he did not know. He had used the German instead of the French radium. Some of his specimens had varied from 17,000 radio-activity up to a larger radio-activity, until finally he was able to obtain one specimen with 1,800,000 radio-activity. He regretted to say that his experience had not been satisfactory with the use of radium.

Gastrostomy in Œsophageal Stricture.—Dr. James H. Dunn of Minneapolis, Minn., said that cicatricial stricture was the most serious benign affection of the œsophagus. Retrograde and through and through treatment of certain œsophageal strictures had been recognized since the operation of Loretta, in 1883; but discoveries and improvements in operative technique had finally completely changed the situation, leaving surgeons in a position to approach one of these cases with a very safe and certain technique, and to fill the following indications: (1) A gastric fistula which would not leak, and close spontaneously. (2) To get a reliable guide through the canal with perfect safety and certainty. (3) To divide the scar tissue sufficiently. (4) Relative asepsis and rest of the wounded surface, prevention of stagnation of food, and for a time the irritation of its passage. The value of the Stamm-Keder form of gastrostomy was generally understood, but it was only when one fully appreciated by experience that any œsophageal stricture might be commanded perfectly and with precision by means now at hand, through very small gastric fistulæ, even the size of a No. 20 French catheter or less, that all the advantages of the method appeared. The steps of the operation were described. A modification of Dunham's wire and spindle bougies was suggested as somewhat simpler and more

handy. The writer had not found it necessary to use guards to prevent the epiglottis and stomach fistula from chafing. By this plan but one anæsthesia was necessary in each case. The fistulæ had not leaked and had promptly healed spontaneously. A caliber admitting of free swallowing was reached in from one to three weeks, and an approximately normal caliber achieved in from two to four months, after which the tendency to relax had been imperceptible. The author reported three very severe cases, one in a girl, aged nineteen, following typhoid ulceration, and two in children, aged nine and two years, from the ingestion of concentrated lye. Repeated attempts had failed to reach the stomach through the mouth in all these cases.

The Bridging of Nerve Defects.—Dr. Chas. A. Powers of Denver, Col., said the difficulties in the way of preparing a satisfactory paper on this subject were due to the indefinite manner in which nerve suture was treated in medical literature, to the widely scattered and badly indexed material collected and published by Chipault, to the fact that much of the material in the literature of the subject described operations upon animals, that a large proportion of operative cases in men were reported before the establishment of a permanent result, and to the fact that in case of failure, it was not easy to say that a given bad result was due to a faulty technique in the operation itself, as a similar result might have followed direct suture of the fragments. The author reported in detail a personal case of transplantation of four inches of the great sciatic of a dog to the external popliteal of a man. Union was prompt. The fragments stayed in place, and the immediate result seemed to be encouraging, but the ultimate result was a total failure. Examination and report were made eight years after operation. Cases of the bridging of nerve defects gathered from literature showed the following number: Grafting, 22; flap operations, 11; implantations (anastomosis), 10; resection of bone, 7; *suture à distance*, 3; tubulization, 1. Analysis of these cases showed that grafting was a failure and should be discarded, while the results in flap operations and anastomosis were about the same, something over 50 per cent. of the cases being successful. While these last operations were not very promising, they seemed at present to be the methods of choice.

Final Results in Secondary Suture of Nerves.—Dr. Emmet Rixford of San Francisco, Cal, reported three cases of secondary nerve suture, of the ulnar at the wrist, of the musculospiral and the facial at the stylomastoid foramen, six, four, and two years respectively after operation. In the first case the atrophic thenar, hypothenar, and interosseous muscles regained their normal volume and function, save in so far as motion of the fingers was limited by adhesions, the result of fixation and chronic arthritis. In the second case the musculospiral nerve was sutured eight weeks after rupture, complicating a fracture of the humerus. A defect of three centimeters was overcome by shortening the humerus that amount and the result after four years was complete motor and sensory restoration of function, with slight atrophy, one-half centimeter difference in circumference in the forearms. In the third case the facial nerve was severed by a narrow tooth beneath the mastoid process. Complete facial paralysis. Suture at eight weeks after the injury. In order to secure tissue for the sutures, the mastoid process was cut away with the surgical engine, and the external wall of the fallopian canal removed for five or six millimeters. Result after two years: Face symmetrical, when in repose; eye closes in sleep; may be closed at will; angle of mouth, tip of nose and chin can be drawn to the paralyzed side. The prognosis in secondary suture was but little, if at all, inferior to the prognosis in primary suture. In the presence of infection, secondary suture was preferable to primary. All scar tissue should be removed, including the whole of terminal neuroma of central segment, the nerve ends united by absorbable suture with the least possible traumatism. Defects, if not too great, could be overcome by stretching which should be done before section of the nerve ends or by shortening of the bone in certain cases.

Primary Carcinoma of the Liver.—Dr. Leonard Freeman of Denver, Col., reported a case of primary carcinoma of the liver on which he had operated, with freedom from recurrence at the end of sixteen months. After dealing with the different methods of operating, he reported his case in detail.

Thyroidectomy for Exophthalmic Goiter.—Dr. Chas. H. Mayo of Rochester, Minn., in a paper with this title, said the subject of goiter was still unsettled, both as regards etiology and treatment, although hundreds of articles had been written upon it. Recent investigations concerning the lymphatic system and ductless glands rendered the subject very interesting at this time. Exophthalmic goiter was a distinct type, with many symptoms, involving the mental, muscular, digestive, and circulatory functions, the most common being the tachycardia without other cause. While the mortality was comparatively high, it was among those cases which had already run the gauntlet of most known remedies for the disease, and should not be entirely laid at the surgeon's door. The surgical methods were exothyropexy ligation of the thyroid arteries, removal of the cervical sympathetic ganglia, thyroidectomy, and the physiological effect of operations upon other regions. The author and his brother had operated upon 130 goiters; 40 were of the exophthalmic type, and of these, 6 died, as the result of the operation. In the first 15, there were four deaths due to lack of judgment in accepting almost moribund cases. There were but two deaths in the last 25 cases. Very severe cases were subjected to *x*-ray exposures, and with belladonna given internally for a few days or weeks previous to operation. Their own cases showed marked improvement in all who survived the operation. Of these 50 per cent. made a very early recovery, especially of the severe symptoms, such as tachycardia, nervousness, and tremor; 25 per cent. did so after several months, and 25 per cent. were improved, yet suffered from irregular recurrence of some of the major symptoms.

Gallstones in the Common Bile Duct.—Dr. S. H. Weeks of Portland, Me., read a paper on this subject, in which he considered the diagnosis and prognosis, and said that impaction of a gallstone in the common duct rarely caused marked distention of the gall-bladder; it caused dilatation of the branches of the hepatic duct, and might result in pronounced and even fatal jaundice. Obstruction of the common duct was always accompanied by jaundice. The jaundice was intermittent or remittent where the calculus floated in an enlargement of the common duct, because the system would eliminate the coloring matter of the bile in the interval. The cystic duct might be occluded, and give rise to grave symptoms, without there being any trace of jaundice or any history of biliary colic. Jaundice with distended gall-bladder not due to gallstones was presumptive evidence of malignant disease. Jaundice without distended gall-bladder favored the diagnosis of cholelithiasis. The treatment was necessarily surgical.

Dr. A. F. Jones of Omaha, Neb., read a paper on "Primary Splenomegaly, Accessory Spleens, Splenectomy," and reported an interesting case.

Dr. S. J. Mixter of Boston, reported a case in which he removed the upper jaw for extensive osteosarcoma, with an excellent result, considering the formidability of the operation.

Dr. Rudolph Matas of New Orleans, La., exhibited and described a new interdental splint which he had recently devised for the treatment of fractures of the jaw, particularly the lower jaw, without bandages.

Dr. Alexander Hugh Ferguson of Chicago exhibited a patient upon whom he had performed renal decap-

sulation for chronic interstitial nephritis three and a half months ago, with an excellent result.

Officers.—The following officers were elected: *President*, Dr. Geo. Ben. Johnston of Richmond, Va.; *Vice-Presidents*, Dr. Emmet Rixford of San Francisco, Cal., and Dr. James Bell of Montreal; *Secretary*, Dr. Dudley P. Allen of Cleveland, Ohio; *Treasurer*, Dr. Geo. R. Fowler of Brooklyn, N. Y.; *Recorder*, Dr. Richard H. Harte of Philadelphia; *Counselor*, Dr. N. P. Dandridge of Cincinnati, Ohio.

San Francisco, Cal., was selected as the place for holding the next meeting, the date to be decided by the officers and committee of arrangements.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held April 28, 1904.

Dr. A. PALMER DUDLEY, CHAIRMAN.

Occiput Posterior Positions of the Vertex.—Dr. JOHN O. POLAK of Brooklyn read this paper. (See page 55.)

Occiput Posterior Positions.—Dr. S. MARX read this paper. (See page 54.)

Dr. MALCOLM MCLEAN continued the discussion and said that a great deal had been written on this subject, but unfortunately there seemed to be an extension of words without conveying much clear and definite teaching, but the paper of Dr. Polak was the best he had ever heard on the subject of occiput posterior positions.

In occiput posterior positions one of the greatest dangers encountered was from the injudicious interference with forceps. The majority of these cases, if left alone, he said would rotate to the front and become practically normal; but, unfortunately, such labors are very tedious, slow, and uncertain. He had never yet seen a normally acting uterus in occiput posterior positions; therefore, it had been suggested that some malposition of the fœtus causes it to act in an irritable way, with short pains, etc., and the short, inefficient pains, or contractions, kept up an unusual number of hours which was so trying to the patient, to both her mental and physical condition, to the family and to the attending phycisian. Such an existing condition often drove the physician to performing operations in an improper manner and at an improper time. This was his experience in the average run of these cases in the average physicians' hands. The consequence was that when the occiput was at the right sacroiliac synchondrosis, the forceps would be placed to the sides of the child's head before a correct diagnosis had been made. This he had seen done time and again, and the result invariably was that as soon as the forceps was applied with the view of bringing what was supposed to be the high occiput on the left, down and spirally to the front, an obstruction impossible to pass was made mechanically. The result was that the women were very much injured by the operation, and it was only after the forceps had slipped after many wretched and repeated attempts had been made, that it became apparent that a correct diagnosis of the position had better be made. Then it was to late to do much. The position should have been discovered at the earliest moment and then the methods tried that were advocated by Dr. Polak.

Dr. McLean said that one of the greatest difficulties encountered in occiput posterior positions was the rotation of the body of the child in order to secure proper anterior position of the occiput. After getting the occiput in the anterior plane it should be kept there; it was easy to get it to the front but very difficult to keep it there. In many of the cases of occiput posterior positions, manual interference was required, because the head was in such a relation to the pelvis that it tended to maintain its posterior position; it was not the result of improper flexion only, but there was a positive tendency of the occiput to remain in the posterior position. He had again and again seen attempts made by different methods to bring the occiput to the right anterior plane, holding the occiput there until a pain brought it down, then forceps applied and there resulted the same old story, the occiput was on the posterior of convex side of the forceps. Now, why? In a great many cases the body of the child influences the head, and, in many cases, this influence was produced by the cord being passed around the shoulder and neck of the infant. Therefore, when attempts are directed to bring the shoulders around they will not come beyond a certain point, they will just describe a certain part of the arc of a circle and no more. Continual attempts to produce this mechanical rotation produces torsion of the spine of the child, because of the fixation of the body. The moment that difficulty of this kind is encountered he caused the occiput to rotate all the way around to the left anterior and this with perfect ease. He had gone to see cases prepared to do podalic version and had found the cord, in some cases, was only six inches in length from the placenta to the shoulders of the child. The cord was shortened by the position of the child, and in such cases he said it was much easier to take the long circuit and bring the occiput to the left anterior plane rather than to the right; thus bringing the body of the child right around and unwinding the involved cord which had acted as a check to rotation in the opposite direction to the right.

Dr. EGBERT H. GRANDIN said that about ten years ago, at a meeting of the American Gynecological Society, held in Brooklyn, he read a paper before an audience composed of men from all over the United States and dealt with the same topic, occiput posterior positions. At that time he had charge of two maternity services, and it had then been his experience to see sixteen cases of occiput posterior positions within six weeks. He made that statement and surprise was expressed at the frequency of the position. He said he was glad to know that the prevalence of this position was now clearly recognized. To his mind it was the most common position which called for interference in the ordinary type of obstetrics. Nowadays he did not do much obstetrics, but in 95 per cent. of the cases in which he was called in consultation he felt pretty sure that he was being called to see cases of occiput posterior positions, as a rule in the cavity or impacted at the outlet. The conclusion which he reached ten or twelve years ago had suffered but very little modification as the result of a greater experience. As a rule, occiput posterior positions occurred because there was some disproportion between the presenting part and the pelvis, either the pelvis being too small or the fetal head too large.

Dr. Grandin said that he failed to see how the "new school" could recognize an occiput posterior at the brim or in the cavity, because this school tried to tell us *not* to make internal examinations but to rely entirely upon external manipulations for diagnosis. He did not think the average man could recognize such malpositions by external examination. With the occiput posterior and at the brim, with the membranes unruptured, with the cervix dilated or dilatable, it was his custom to do a podalic version followed by quick extraction of the child. In that class of cases with membranes ruptured and the head descended posteriorly into the cavity, he asked what should be the rule of procedure? It was in this class of cases that the reader of the paper used axis traction. Dr. Grandin said that if it was simply a question of merely rotating the head he would agree with the method advocated but it was not simply a question of rotating the head. The head could be rotated through a certain circuit without damaging the fœtus, but one could not rotate it a great ways without killing the child because the trunk of the child would not follow the head in its rotation. Therefore, he thought the method advocated was not rational. The object should not be rotation of the head but rotation of the body of the child and here was where the point raised by Dr. McLean entered in; rotate both head and body and while the patient was under

deep surgical anæsthesia; the entire hand in the vagina should grasp, not the head, but the shoulders of the child and rotate the fœtus in the direction it went the most easily. If one tried to rotate it to the left and found it would not go it meant that the cord was interfering and then rotation should be made in the other direction. If the head was found at the outlet and impacted he said there was but one thing to do in the interest of the mother, operate upon the child. Of late years he said he had learned more about this class. Dr. Isaac Taylor, two or three months before his death, asked Dr. Grandin to select from his stock of instruments what he desired and then, after his death, to give the balance to the Maternity Hospital. Dr. Grandin selected a short-handled forceps, which he carried nowadays with his action traction forceps and angiotribe. If the head was impacted at the outlet, with a living child, he applied these short-handled forceps in the inverted sense and so secured flexion; flexion once secured one could then deliver the child. Get flexion and deliver, although with loss of integrity of the pelvic floor. Dr. Grandin said that ten years ago he was severely criticised when he advocated manual manipulation at the brim; now he advocated version.

Dr. Joseph Brown Cooke agreed with all that Dr. Grandin had said and believed that occipitoposterior positions were much more common than generally supposed. It was an easy presentation to diagnose by abdominal palpation. In his experience he had found the postural method to be of but little value because the rotation of the head was almost always to the front in spite of it. He believed it to be inexcusable for anyone to attempt to apply the forceps without a definite knowledge of the presentation. Before the application of the forceps there should be a dilated or a dilatable cervix and the patient should be completely under the influence of the anæsthetic.

Dr. Robert A. Murray referred to an unusual number of cases of occipitoposterior presentations that had occurred at the Maternity Hospital between the years 1890 and 1893, and he thought this was due to the fact that there were so many women of foreign birth and with deformed pelves. Whenever such a position occurred he said that it was necessary to determine *why*. It was, as a rule, not due to the size of the child but to some malformation of the pelvis. One should know exactly just what the size of the child's head was and its relation to the pelvis, and if this could not be done readily then the patient should be placed under complete anæsthesia and the hand introduced into the pelvis for a more thorough examination. The mortality in these cases he considered to be very great, and was apt to be complicated with embarrassing circumstances, such as lacerations, eclampsia, prolonged labors, bleeding, etc. He believed that many of these cases should be treated by version. In most of the textbooks it was stated that, in the mechanism of occipitoposterior positions, the head instead of extending was forced down to the floor of the pelvis and gets under the spine of the ischium and then commences to rotate, *i.e.* cannot rotate until it gets beneath that spine. Dr. Murray said that it could if one endeavored to correct this extension by efforts at flexion, pushing up the frontal portion and so allow the forehead to come down. He said that out of one hundred cases of occipitoposterior positions four or five would rotate into the hollow of the sacrum. In these cases it was very difficult to apply the forceps; to apply them transversely was almost an impossibility. One could not pull the head straight down because of the great damage done; the child might be killed and the mother greatly injured.

During the years 1890 and 1893 there were 957 cases; among these there were 119 low forceps operations and 12 high forceps. In 9 labor was induced, in 4 there was eclampsia, in 6 hemorrhage, in 28 version, in 1 cæsarean section was performed, in 1 laparotomy, in 7 craniotomy, and in 7 episiotomy. Among these cases there were 4 deaths, 3 from eclampsia, and 1 from ruptured uterus. There were no deaths due to the use of forceps or to version.

Dr. A. Palmer Dudley said that his experience in these cases had been purely surgical. He said he had never done a craniotomy and had had one case of ruptured uterus.

Dr. S. Marx said he was not so much afraid of occipitoposterior positions as he once was. The early operative treatment of these cases he believed to be a mistake. When there was occasion to operate one should operate quickly and before the membranes ruptured if possible. He did not know how many of occipitoposterior presentation he had seen but in not one of them had the membranes *not* ruptured early. If the membranes had ruptured he would hesitate to interfere because in 90 per cent. of the cases rotation would occur spontaneously during the course of the labor. Manual rectification had not been successful with him. If he should find it necessary to go into the uterus and if he was in a position to do version he said he would do an elective version. If this was undertaken late in the progress of labor it would be a difficult thing to do, and then it might be a better procedure deliberately to perforate the child's head. Dr. Grandin stated that by rotation with the axis traction forceps, it would wring the child's neck; he asked if the same thing would not occur with the hand in the uterus and attempts made at rotation.

Dr. Robert A. Murray said that when he made the statement regarding the correction of the position of the child's head, he meant that the hand should be passed up to grasp the shoulders and efforts made at rotation of the shoulders as well as of the head.

Dr. Marx said that he did not believe the question of contracted pelvis entered at all into the consideration of this subject any more than the consideration of the condition of the child's head in its relation to the spinal column. If the child was in the dolichocephalic condition in position with the spinal column in the middle part of the base of the skull there would be a question whether the head would extend or take a position of semi-flexion. The relation of the head to the spinal colume should be kept in mind. The moment it struck the superior plane of the pelvis flexion occurred and, in the mechanism, more had to do with the condition of the child's head. The question arose as to what constituted a "contracted pelvis." He did not know unless it meant that the head was too big for the pelvis.

With regard to making a diagnosis of occipitoposterior positions by external manipulation alone he agreed with Dr. Grandin in what he said in reference to the so-called "new school." This new school made the diagnosis so easily because in 95 per cent. of all cases the head presents and, when certain things operated, it was only necessary to say "occipitoposterior position" and you would almost always be correct. He said that he examined as often as he deemed it necessary and guided the head with his hand in the vagina around to the anterior.

With regard to the rotary axis traction he said he was not often compelled to use it. In spite of what Dr. Grandin said in criticism of it he believed that Dr. Grandin would use it before he died.

It was rather interesting for him to hear Dr. Murray speak of the cases occurring in the early 90's because those cases occurred while he was assistant surgeon to the Maternity Hospital and were his, Dr. Marx's, own work. In a great many cases he believed that perforation should be the method of election. During every year he had about one dozen perforations to do in his consultation practice.

Dr. George Tucker Harrison took issue with those who said they should make as many examinations as they choose. He believed the fewer examinations made the better, because of the difficulty of getting the hand perfectly aseptic. He did not apply forceps to correct

positions of the head; if the head was high he preferred podalic version. With this method he had satisfactory results and, therefore, did not care to change.

Dr. JOHN O. POLAK closed the discussion and said that he believed all were in accord with the position assumed by him, *i.e.* in cases of head above the brim, treat by version; and in those cases with the head engaged in the cavity or on the floor, treat by forceps. In those cases of occipitoposterior positions with the membranes unruptured he believed in giving Nature a trial and not interfering. In a case with membranes ruptured, with the head at the brim, if the head was engaged in the pelvis and could be rotated to the front with rotation of the body, it then was better to deliver by forceps than to attempt version, if the operation was to be done by one not an expert. He said this because all were not experts in the management of the after-coming head and in extracting the arms.

The position taken by Dr. Marx regarding craniotomy he said deserved praise and also comment. He had seen two cases of rupture of the uterus caused by the application of the forceps when the head was not engaged, while at the pelvic brim and in both of these cases the child was dead. It was to him surprising how many difficulties could be overcome by intelligent craniotomy, and for three or four years he had been doing craniotomy when the mother's life was endangered.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending July 2, 1904:

	Cases.	Deaths.
Measles	369	23
Diphtheria and croup	386	50
Scarlet fever	130	9
Smallpox	1	1
Varicella	61	...
Tuberculosis	330	150
Typhoid fever	33	12
Cerebrospinal meningitis	...	39

A Strange Result of Iodoform Dressing.—H. McNaughton-Jones reports this case. The patient, a woman of thirty, had recently undergone an abdominal operation. The course was favorable until the third day after the operation. Irritation and some smarting in the neighborhood of the wound was then complained of. The wound had been stitched with celloidin-zwirn, a pad of moist sterilized 10-per-cent. iodoform gauze being placed over it covered with coeletin. On raising the dressing the nurse found some slight swelling and redness along the area of the incision. The irritation increased and the next day the iodoform was removed and the wound lightly sponged over with some weak formalin solution, dried and dusted with dermatol, covered with plain sterilized gauze, and protected with coelitin. The distress continued and the next day several large vesicles appeared. The arms and hands now became involved, later the legs. There were no constitutional symptoms. The skin healed by first intention. It was learned that many years before the patient had had an ulcer on the leg. This had been dressed with iodoform with much the same results as in the present instance. From her childhood the patient had suffered from an eczematous tendency.—*Medical Press and Circular*, February 24, 1904.

Report of a Case of Perforation in Typhoid Fever in a Child of Six Years.—John H. Topson describes this case. The child was a male Hebrew child who had been healthy up to the time of this present illness. For two weeks he had been suffering from malaise, fever, cough, and headache. Diarrhœa and abdominal pain developed, which seemed to be located in the right iliac region. The day before his admission to the hospital he began to vomit. Examination showed his lungs to be clear. The abdomin was distended and tender, particularly in the right iliac region. There were a few suspicious spots. Projectile vomiting developed. When seen by the writer, the temperature was 98.8° F., pulse 120, respiration 48 There were noted, abdominal distention, generalized rigidity, tenderness, especially in the right iliac region, absence of liver dulness, thoracic type of respiration, and absence of peristaltic sounds. The general condition was fair, considering the advanced local symptoms. A diagnosis of intestinal perforation during typhoid fever was made. Operation showed the perforation to be in the ileum, about eight inches from the colon, about the diameter of an ordinary lead pencil. The after-history was like that of many cases of operation in the presence of general peritonitis. Improvement followed for twelve hours, but at the end of the first day vomiting and other signs of peritonitis occurred, the pulse weakened, and at the end of seventy-two hours the patient died. The perforation probably occurred at least twenty-four hours before operation. After death the perforation was found to be firmly occluded and water-tight. Perforation is rarely encountered at such an early age as in this child. The writer believes that the case of this patient is possibly the youngest yet reported.—*Archives of Pediatrics.*

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended July 2, 1904.

PYELITIS COMPLICATING PREGNANCY.*

BY EDWIN B. CRAGIN, M.D.,
NEW YORK.

THE occurrence during pregnancy of a marked rise of temperature with pain and tenderness on the right side of the abdomen is always a source of anxiety to the obstetrician, and its diagnosis and prognosis are matters which deeply concern him.

Although several able articles, by Vinay,[1] Reed,[2] Brigand,[3] Häberlin,[4] and others, have appeared describing the condition, it is not generally recognized by either specialist, or general practitioner, that pyelitis is a not infrequent cause of the above symptoms.

The condition was first accurately described by Reblaud at the surgical congress in 1892. That it is not rare in occurrence is evidenced by the fact that during the past winter the writer has met with five cases in private consultation work, and including these has seen ten since September, 1900.

The etiology of the condition seems to depend, according to Vinay, upon two factors: (1) Compression of the ureter by the pregnant uterus. (2) Infection of the urinary tract above the point of compression.

1. Compression of the Ureter by the Pregnant Uterus.—Experiments upon animals have shown that the urine is excreted under low pressure. Ludwig demonstrated that the pressure in the renal pelvis normally does not exceed 10 mm. of mercury. It requires, therefore, but little compression of the ureter to retard the current.

That compression of the ureter with resulting dilatation does occur in pregnancy is proven by the records of autopsies on pregnant women by Stadfeld, Olshausen, Loehlein, and others. Stadfeld in 16 autopsies on pregnant women, found 9 dilated ureters. In all the writer's cases and in all the authentic cases of pyelitis in pregnancy which he could find reported the lesion was primarily right-sided and usually confined to the right side. Many explanations of this have been given. According to Olshausen,[5] the right ureter is the one most often compressed and dilated in pregnancy. In 16 cases of dilated ureter found by him in autopsies on pregnant women, 12 were unilateral, and of these 12, 10 were right-sided and two were left. As causes of the greater compression of the right as compared with the left ureter the following have been suggested:

1. The greater prominence, at the brim of the pelvis, of the right over the left common iliac artery exposes the right ureter to greater pressure between the uterus and the iliac artery of that side.

2. The rotation of the uterus on its long axis from left to right, forward, places the uterus and its contents more in the right oblique diameter of the pelvis than in the left, and thus exerts more pressure upon the right ureter than upon the left.

3. The greater frequency of the fetal head in the right oblique diameter of the pelvis increases the frequency of pressure upon the right ureter

In support of this view may be mentioned the fact that in 8 of the writer's cases the position of the fetal head was noted, and in these 8 cases, the head occupied the right oblique diameter in 7; there being 6 in the L. O. A. position, and one in the R. O. P.

Theoretically one would expect, from the greater tone of the abdominal and uterine walls, more compression, and hence more cases of pyelitis, in primigravidæ than in multigravidæ, and that was borne out in my cases, there being 7 primigravidæ and 3 multigravidæ. This is contrary to the experience of Vinay, among whose 9 cases there were only 2 primigravidæ and 7 multigravidæ.

2. Infection of the Urinary Tract above the Point of Compression.—From the frequent appearance of the bacillus typhosus in the urine of typhoid-fever patients and from experiments on animals, it would seem that in many infective processes the organisms may be eliminated by the urine without appreciable injury to the urinary tract, provided this tract is in no way obstructed. On the other hand, the experiments of Reblaud and Bonneau on animals show that after an aseptic ligature of the ureter, the injection into a distant part of the body of either streptococci or colon bacilli can produce a pyonephrosis, it being a descending infection.

Hence with a ureter compressed by the pregnant uterus, the infection of it and the renal pelvis is favored. The infecting organism in the pyelitis of pregnancy is usually the colon bacillus. This was the organism found in three of my cases, the only ones in which the urine was examined bacteriologically, and has been found to be the infecting organism in all reported cases examined bacteriologically with two exceptions—one by Vinay, in which the streptococcus was found, and one by Lop which showed the gonococcus.

The period of pregnancy at which the pyelitis is most likely to occur is between five and eight months. In all but one of my 10 cases the attack appeared at that time. In 3 it occurred at five months; in 2 at six months; in 3 at seven months; in one at eight months, and in one at term.

During the last two years I have also met with three cases of pyelitis developing during the puerperium. These were probably of the same origin as those occurring during pregnancy, and recovered under the same treatment, but as no bacteriological examination of the urine was made, and as ascending infection could not be positively excluded, they are not included in the present discussion.

The general course of pyelitis in pregnancy may be seen from the following brief abstracts of cases which have come under my observation:

CASE I.—Mrs. F. G., aged twenty-five, IV gravida. Admitted to the Sloane Maternity Hospital, September 13, 1900. For five weeks previous to admission she had suffered with frequent and painful micturition, and for the last three weeks with pain in the right lumbar region, increased by coughing or other

*Read at a meeting of the American Gynecological Society in Boston, May 24, 1904.

motion. For the week previous to admission there had been a rigor each morning, followed by fever, sweating, and headache. On the day following admission, her temperature was 102.6° and there was tenderness over the right kidney. Her urine was acid and contained many pus and epithelial cells. She was delivered of a full-term child September 15, two days after admission. Position of child L. O. A. On the day following delivery the afternoon temperature was 103.8°. She was given a urinary antiseptic, and on the fifth day the temperature came to normal and remained so thereafter. The urine gradually became clear. Her highest temperature while in the hospital was 103.8°. It remained above 100° for four days.

Case II.—Mrs. L., aged twenty-three, primigravida. Admitted to the Sloane Maternity Hospital, August 31, 1901. She was in the seventh month of pregnancy, anæmic, and complained of pain over the right side of her abdomen. Her urine showed pus cells and a trace of albumin. Her temperature on admission was 102.8°. She was given a urinary antiseptic, fluid, diet, and large draughts of water. Her temperature and tenderness over the right kidney subsided in four days and the urine gradually cleared. Her highest temperature was 102.8°. It remained above 100° four days. She was normally delivered November 11, 1901, and made a good convalescence. The position of the child was L. O. A.

Case III.—Mrs. M. G., aged twenty-three, III-gravida. Admitted to the Sloane Maternity Hospital, September 19, 1901, complaining of severe pain in the right lumbar region. Her pregnancy was seven months advanced, and she stated that she had had fever in the afternoon for several days. Her urine was acid and showed pus and epithelial cells. There was a trace of albumin. Her temperature on admission was 102.8°. She was given a urinary antiseptic, milk diet, and large draughts of water. Her temperature reached normal on the eighth day and remained so thereafter, the urine gradually clearing. Her highest temperature while in the hospital was 104°. Her temperature remained above 100° for seven days. She was normally delivered two months later. Position of child L. O. A. Her puerperal temperature did not reach 99°.

Case IV.—Mrs. M. H., aged thirty-seven, XIII-gravida. Admitted to the Sloane Maternity Hospital, April 20, 1903, complaining of sharp pain over the right kidney. Her urine was acid and contained pus and epithelial cells. Her pregnancy was seven months advanced. By May 12 the pain had ceased and the urine was nearly clear. At no time during her stay in the hospital did she show any rise of temperature above 100°. The position of child was R. O. A.

Case V.—Mrs. D., aged twenty-four, native of United States, primigravida. Admitted to the Sloane Maternity Hospital, May 18, 1903, stating that for two days she had suffered with pain in the right lumbar region and fever. On admission her temperature was 102.4°. Her urine was acid and showed pus and epithelial cells. Her leucocytes numbered 22,000. She was delivered of a full-term child on the day following admission. Position of child R. O. P., rotating to R. O. A. In spite of urinary antiseptics, ice-bags to the kidney, fluid diet, and large draughts of water, the patient gradually grew worse, and on June 3 the right kidney was removed by Dr. Joseph A. Blake. The kidney showed several small abscesses in its substance, and bacteriological examination showed the colon bacillus. After a tedious convalescence the patient completely recovered. Her highest temperature previous to the nephrectomy was 104°. Her temperature prior to the nephrectomy was above 100° for sixteen days.

Case VI.—Mrs. M. G., primigravida, seen in consultation with Dr. Palmer A. Potter of East Orange, N. J., October 14, 1903. Her pregnancy was five months advanced. She had had an irregular fever for several days with an occasional epistaxis. Her temperature when I saw her was 104°. For three days prior to my visit she had complained of pain in the right lumbar region. The case looked a good deal like typhoid fever, and that was my first probable diagnosis. The Widal test, however, was negative, and subsequent examination of the urine showed it to be acid with pus cells, renal epithelium, bacteria, and a trace of albumin. She was given a urinary antiseptic, fluid diet, and large draughts of water. On the third day following the commencement of the urinary antiseptic, the temperature came to normal and remained so thereafter. Her highest temperature was 104°. Her temperature remained above 100° for nine days. The urine gradually cleared. She subsequently went to term and was delivered of a living child. Puerperium normal.

Case VII.—Mrs. G., aged twenty-six, primigravida, seen in consultation with Dr. George E. Steel of New York, December 13, 1903. She was six months pregnant, and for forty-eight hours had been complaining of pain on the right side of the abdomen in the region of the vermiform appendix. Her temperature was 102°, pulse 130. The site of greatest tenderness was near the McBurney point. It looked like a case of appendicitis, and that was my probable diagnosis on my first visit. Examination of the urine next day, however, showed it to be acid and to contain pus cells, hyaline casts, and albumin. Previous to the attack of pain, the urine had been normal. The diagnosis was changed to that of pyelitis, and she was given a urinary antiseptic with fluid diet, large draughts of water, and an ice-bag over the right kidney. Her pain and temperature subsided in three days and she made a speedy recovery, although the urine showed pus cells and casts for more than a month. Her highest temperature was 102°, highest pulse, 130; the temperature remained above 100° for four days. She was delivered at term, March 10, 1904. Position L.O.A. Puerperium normal.

Case VIII.—Mrs. C., aged twenty-seven, primigravida, seen in consultation with Drs. C. T. Adams and F. F. Ward of New York, March 4, 1904. She was five months pregnant, and for the month previous had complained of pain and tenderness on the right side of the abdomen, especially in the region of the right kidney, which could be felt enlarged and tender. Her temperature during the month prior to my visit had been a varied one, ranging from normal to 104° with intermissions of several days when the temperature was normal. No malarial organisms were found and the Widal test was negative. Her urine was acid and contained pus cells, a trace of albumin, and a few hyaline casts. The diagnosis of pyelitis was made and she was given a urinary antiseptic, fluid diet, and large draughts of water with an ice-bag over the right kidney. Her temperature and pain subsided in two weeks after beginning the urotropin, but the urine contained pus for a month longer. Her highest temperature was 104°, highest pulse 118. Her temperature was above 100° for sixteen days. She is now progressing normally in her pregnancy.

Case IX.—Mrs. P., aged twenty-four, primigravida, seen in consultation with Dr. D. E. O'Neil of New York, April 10, 1904. She was about six months pregnant and for three weeks had been

complaining of pain on the right side of her abdomen. She had had several slight rigors. Her micturition had been frequent and painful. On examination her right kidney was found enlarged and tender. Her urine was acid and contained considerable pus. The filtered specimen showed no albumin. Cultures from a catheterized specimen showed the colon bacillus. She was given a urinary antiseptic with fluid diet and large draughts of water. Her temperature and pain subsided in about ten days after beginning the urinary antiseptic. She is now progressing normally in her pregnancy, but the urine still contains a little pus. The position of the child is L. O. A.

Case X.—Mrs. B., aged twenty-eight, primigravida, seen in consultation with Dr. Edwin Sternberger of New York, April 29, 1904. She was about five months pregnant, and for two days had been complaining of pain on the ride side of the abdomen, especially in the appendicular region and in the back. This pain at times was intense. Her urine was acid, contained a trace of albumin, considerable pus, and the bacteriological examination showed abundant colon bacilli. Her right kidney could be palpated, was enlarged and tender. For several days her pain was much worse every other day.

On May 10 her leucocytes were 14,400; red cells, 4,120,000; urea, 296 grains. May 16, leucocytes 16,000. From April 27 to May 6, in spite of the pain in the region of the right kidney and ureter, the temperature did not rise above 100.4°. On May 7 the temperature reached 101.2°, and on May 10 104°. For the next three days she became progressively worse, her temperature on the evening of May 13 reaching 105.6°, and it seemed to me that operative interference would be demanded on the following day. The next morning, however, found the patient better, and under the advice of Dr. Willy Meyer of New York operative interference was postponed. The patient steadily improved, the temperature reaching normal in four days. This case has been characterized by more pain than any of the others under the observation of the writer. Opiates in some form have been frequently required. Her highest temperature was 105.6°. It remained above 100° for seventeen days. The temperature at the time of writing is normal, but the pain, although less severe, has not entirely disappeared. Aside from opiates for the relief of pain, her chief treatment has been with urinary antiseptics, fluid diet, and large draughts of water.

From the above cases the symptom-group can fairly well be pictured:

Pain in the right lumbar region sometimes very acute, sometimes only elicited by palpation or motion. The pain often follows the course of the ureter from kidney to bladder. *A rise of temperature*, usually quite high at some time during the attack, 102° to 105°, although in one of my cases (Case IV) the temperature did not reach 100°. In cases with high temperature rigors are not infrequent.

Irritability of the bladder with frequent and painful micturition is common, but the infection is a descending one, and the cystitis, when it does occur, is usually secondary to the pyelitis and ureteritis. *The right kidney can usually be made out enlarged and tender. The urine is acid, at first may contain only a trace of albumin and perhaps a few casts, to be soon followed by pus cells, renal epithelium, and bacteria.* The filtered urine often shows no albumin. The pus cells are usually more abundant as the pain and temperature subside. The urine often contains pus cells for a month or more after the constitutional symptoms have disappeared.

One of the features of chief interest in pyelitis complicating pregnancy is the diagnosis. In many cases this is easy if the possibility of the condition is borne in mind. Pain and tenderness in the region of the kidney, a rise of temperature, and an acid urine containing pus may point at once to the diagnosis of pyelitis. On the other hand, it must be remembered that when an abdomen is occupied by a uterus pregnant from five to eight months the palpation of the other abdominal organs is often difficult. Furthermore, there are other conditions which may give symptoms resembling it. The three conditions most likely to be confused with pyelitis in pregnancy are, judging from the writer's experience, appendicitis, typhoid fever, and salpingitis.

In some of my cases, especially Cases VII and X, the point of greatest tenderness has corresponded closely with the McBurney point, and appendicitis has been strongly suggested. In each of these cases the diagnosis was made from the condition of the urine. The reason for the point of tenderness corresponding with the McBurney point seemed to be that pressure at this point forced the uterus back against the ureter and thus increased the pain. The leucocyte count in these cases of pyelitis resembling appendicitis has seemed to the writer lower than one would expect in an appendicitis case correspondingly ill.

In Case VI the irregular fever and the epistaxis resembled typhoid fever, and it was only after the negative Widal test, the explanation of the epistaxis by the amenorrhœa of pregnancy, and the examination of the urine that the correct diagnosis was made.

The differential diagnosis between pyelitis and salpingitis can usually be made by the history, the bimanual examination, and the careful examination of the urine.

From the above cases it will be seen that the chief aid to the diagnosis of pyelitis in pregnancy is the careful examination of the urine; chemical, microscopical, and bacteriological.

Although the pain may be very severe and the temperature high, even 104° or 105° for a few days, the prognosis of pyelitis complicating pregnancy is usually good. With the exception of Case V, in which the pyelitis started at term and in which the substance of the kidney was infected as well as its pelvis, all the cases of my series recovered under medical treatment, the temperature and pulse subsiding to normal in from four to thirty days; the urinary changes perhaps persisting for a month more.

Judging from my own cases and from the reported experience of other observers, if the kidneys have previously been healthy, pyelitis complicating a pregnancy of from five to eight months advancement, which is the usual period of the complication, justifies a favorable prognosis of complete recovery under medical treatment.

In a few cases, however, there are recurrences during the pregnancy, and the possibility of a pyelitis becoming a pyelonephritis, as occurred in case V, just referred to, must not be lost sight of. This latter possibility seems more likely the nearer the complication approaches full term and the puerperium.

The medical treatment which the writer has employed in all the cases under his observation is as follows: Rest in bed; fluid diet, especially milk; large draughts of water; urinary antiseptics; ice-bag over the kidney, and, if this fails to relieve the pain, an occasional opiate. In many cases, saline catharsis has given marked relief. If, in spite of this treatment, there is evidence of extension of the infection

to the kidney substance, surgical interference by nephrotomy or nephrectomy is indicated.

Interruption of the pregnancy is seldom, if ever, necessary or advisable.

THE TRUE EDUCATION OF MIND AND BODY.*

By RICHARD COLE NEWTON, M.D.,
MONTCLAIR, N. J.

To anyone who stops to think a moment, it must be very plain that there is an incalculable waste of power and energy in human life. Man's spiritual, mental, and physical powers are capable of almost infinite development. It is true that we are hampered by many limitations, the span of our life is so short, and so much of this brief space must be given up to learning what has already been done by others in any particular field, not to mention the entire purview of human knowledge, that there is only a short time left for original investigation. Furthermore, only a fairly brilliant mind is capable of absorbing the existing store of human knowledge in any one profession or science, and only comparatively few men and women have the opportunity, the industry, and the physical and mental strength to become really learned. This, however, is by no means equivalent to saying that any man during his life on earth makes the best practical use of his time and opportunities.

Most men are engaged in the sordid pursuit of money, and spend a great deal of energy and thought in endeavoring to circumvent their fellows and accumulate money which may never benefit them. The struggle for bread is so fierce and our love of ease, of sensual enjoyment and social distinction is so pronounced, that nine men out of ten think they have no time for self-improvement, either mental or physical. This is far from true. Practically any man or woman might be wiser, happier, and healthier than he or she now is. There is unfortunately an inadequate and one-sided notion of education prevalent in America. Not only do we ordinarily neglect the physical side of education, but we are wont to look upon a college degree as itself an end, and as the distinguishing mark of an educated man. Whereas it at best only marks the end of one period of his development. The only true and satisfying attitude of the mind toward education is that of the historian, Freeman, who wished it to be said of him that he died learning. Neither the mind nor the body can safely be allowed to stagnate. If there is no progress there will surely be retrogression.

A non-functionating attribute invariably deteriorates. This is an immutable law of nature, and is perhaps in no respect more strikingly manifested than in the non-developing minds of those who do not study. A man's conduct may improve and his experimental knowledge of the world increase with years, but unless he actually studies and exercises his mental faculties, his intellectual horizon will not broaden, nor his mental vigor increase as he grows older. On the contrary, his prejudices will take deeper root and the bonds of conventionalism will bind him more closely. This mental inactivity we call conservatism; but it is really a state of mental inertia, in which prejudice, or a blind adherence to previously formed opinions, takes the place of thought and independent judgment.

Of course the majority of non-thinkers have never exercised their minds enough to have learned to think clearly and logically. Stevenson said that he "had only to read books to think, but the mass of people are only speaking in their sleep." How often do we see professional men, teachers and others, who have reached an intellectual status after which any further progress seems impossible. What is more lamentable than a self-satisfied professional man, who fancies that he has nothing more to learn? Unfortunately he is no exception to the universal law, and if there is no advance in his mental condition, there will be recession.

A principal, if not the principal, cause of human unhappiness is the mental unrest, which is caused by the unsatisfied craving for the exercise and development of our God-given intellectual powers. This craving is born in all mankind, it has been called the divine unrest, because it leads man ever to struggle toward knowledge, toward righteousness, and toward freedom. Only the minds that have freed themselves by powerful and regular exercise of their own functions can shake off the shackles of superstition and the bonds of fear. Only minds so disciplined can be at rest and await with calmness the unfolding of fate, can bear with fortitude the struggle with their own limitations, and the increasing bodily infirmities which tend to occlude their vision and thwart their best efforts. Of such a mind the good Sir Edward Dyer said three hundred years ago: "My mind to me a kingdom is." Nor is the development of the highest type of mind possible without a healthy and vigorous body. Nor can this, on the other hand, be developed without persistent, careful, and properly regulated exercise. In other words, leaving out of consideration those human anomalies whom we call geniuses, there is no way that a man can fit himself to do good work, either mental or physical, except by a thorough, painstaking development of his mental and bodily powers.

Unfortunately the average man leads, strictly speaking, no intellectual life. He does not really think, he does not read anything that requires mental exertion, he does not study. And if we turn our thoughts to the gentler sex what do we find? A remark of Harriet Martineau's that the poor health of American women was due to the vacuity of their minds, was unquestionably in a measure true. This was made, of course, some years ago, before the proliferation of the female college, and the entrance of women into the professions, etc. On the other hand, an editorial in a leading medical journal about a year ago, in commenting upon the comparative sterility of American women, says: "But with her growth in brain power, she has declined in physique." To this statement the writer takes unqualified exception. American women in our day have smaller families than their ancestors it is true, but proof is entirely lacking that they are of inferior physique, and their comparative sterility is due chiefly to an improper and unphysiological avoidance of conception. This is not to say that there are not numerous cases of nervous breakdown amongst women, educated and uneducated, from overstudy, overwork, etc. However, the percentage of American women injured by overstudy must be inconsiderable compared to the whole number of women of childbearing age.

The faulty methods of education now prevalent are but too obvious and there is no question about the handicaps which bear upon every woman who undertakes to develop her mind. Nor can the ex-

*Read before the Morristown Medical Club.

periment of giving a woman a man's education be successfully carried out in general, unless girls shall be fitted for the contest by a better heredity and a more physiological method of life. They must develope their muscles and their lungs and live more in the open air in childhood, and grow up without the impediments of corsets, high-heeled shoes, tight clothing and similar abominations, which cramp and distort their growing members, impair their digestions and lay the foundation for the nervousness, dyspepsia, and the numerous bodily infirmities of after years.

What women suffer from chiefly is want of physical development. Had they man's muscu'ar strength they could easily outstrip him in mental acquirements, for at least the first few years of life, by reason of their quicker and more elastic minds, their greater devotion to their duties and their greater freedom from dissipation and immorality. The mistake that our educators have made is to take advantage of the girl's willingness to work her intense love of approbation and her more rapid mental expansion, which is commensurate with her rapidly developing body, at the age of puberty, to force her along too fast without regard to the consequences. A woman's bodily health will be as surely benefited as a man's by a thorough intellectual development, but she is more easily injured in the process because she is without any question the weaker vessel.

I had begun to hope that the once prevalent notion hat a man cannot be learned and physically strong at the same time, was becoming *passé*, and yet in a book on health copyrighted last year the following appears: "It is an error also to think that great muscular development is desirable in a brain worker. The two are incompatible." This is one of the hoary fallacies which have encumbered medical literature, and misdirected medical thought from time immemorial. One would fancy it to have been originally the *ipse dixit* of some lazy and ill-developed medical writer, who having no muscle himself and being too indolent to acquire any, soon proved to his own satisfaction the undesirability of having any. And subsequent medical writers have slavishly followed this erroneous light, as they have many others. There was a kindred notion prevalent a generation ago from the tyranny of which we have by no means entirely escaped, viz., that a man is born into the world with a certain fixed amount of energy, which he is at liberty to expend in any way he chooses, but cannot replenish; so that if our physical side is developed, our mental must be dwarfed. Can anything be more absurd, or more at variance with nature's well known laws? And yet, I well remember a professor of philosophy, whose name is known on two continents teaching that very doctrine to his class, of which I was a member, about thirty years ago; and there are many prominent teachers, preachers and medical men, who believe or affect to believe the same fallacy to-day.

I remember reading in my boyhood in an excellent family paper called the *Evangelist*, this same false doctrine, which made a deep impression on my youthful mind and gave me serious doubts as to whether it was right for me to work in the garden in conformity with my father's commands, because it seemed a serious thing to impair my chances of acquiring an education, merely for the sake of raising a few vegetables. And it also filled me with consternation to reflect that this vigor or energy, which it was assumed that we must carefully conserve for the development of our brains, might be so easily dissipated, and could not be expended at the same time on both bodily and mental exercise any more than one can both eat his cake and keep it.

That the *Evangelist* meant well in general on matters of hygiene was evidenced by the sentiments expressed in an editorial article upon washing the feet, which also deeply impressed my boyish mind, and I may say had a decidedly favorable influence upon my habits. As I remember it now, the gravamen of the article was that the feet should be washed several times a week, instead of once; and the statement was made that the skin of the feet has great powers of absorption, and that the offensive matter which is excreted through its pores would be reabsorbed into the system were it not washed off.

This, so far as it goes, is true, and the advice is sound and may be applicable to-day to at least some of the readers of the *Evangelist*.

Even in those dark ages of sanitary science there were glimmerings of the greatly aroused interest which we at present note on this important subject. And the fact that an influential religious paper and the organ of a branch of the Presbyterian Church, did not esteem an editorial upon washing the feet beneath its dignity nor out of place in its editorial columns, was an evidence of good sense, and reflected credit upon the editor. It showed further that the readers of that paper, like the readers of current literature to-day, wanted more light, perhaps I should say needed more instruction, upon the proper methods of living.

No one in our time who reads the newspapers or who attempts to keep abreast with the tendencies of modern American life, can fail to notice the ever-widening interest displayed not alone in athletic sports, but in all matters in any way pertaining to bodily health and development. This is the day of the physical culturist in all his forms and with all his or her different theories, appliances, and maneuvres, by which vigor is to be attained, lost manhood restored, dyspepsia banished, and the doctor avoided. One "professor" offers for the insignificant sum of a dollar to sell to anyone a book containing directions which, if followed out, will save the purchaser from the necessity of ever paying another doctor's bill. There are all sorts of health foods and drinks advertised; all sorts of systems of diet, exercise, and bathing are promulgated. One man teaches that all food of whatever kind should be eaten uncooked. Another denounces the eating of any form of meat, while a third instructs us that the consumption of nuts will give the most strength, which reminds one of the butcher boy in David Copperfield, whose preternatural strength was attributed to the beef suet with which he annointed his hair.

This is the day of the man who advocates chewing each morsel of food thirty-two times, once for each tooth, said to have been a maxim of Mr. Gladstone's. Of the man who goes without breakfast; of him who lives on eleven cents a day; of him who eats no salt, and of him who cooks all the fruit he eats; of him who never takes liquid with his meals, and of him who advocates only one dish for dinner. We are told to sit or lie naked in the sun, to wear only wool next the skin; or linen, or silk, or cotton, according to the predilection or self-interest of the adviser.

The disciples of an alleged school of hygiene in our own State lie naked in the earth for several hours a day. Some one in Chicago is just now preaching against all forms of bathing, while other people advise baths for the cure and prevention of every form of disease. I have heard doctors in good practice advise wearing high-heeled shoes to "maintain the integrity of the arch of the foot," while large numbers of people claim to have received benefit from the Kneipp cure, a part of the regimen of which is to walk barefooted in the dewy grass.

Perhaps the most revolutionary statement which

I have met with lately is that of a "professor" who guarantees to increase the stature of any one paying him $10, and using his method, from two to five inches. This seems to controvert the scriptural statement that one cannot add to his stature by taking thought, but the world moves and our modern "professors" are wonderful fellows.

One teacher advises against diaphragmatic breathing; while others hold that it is the only physiological method of respiration. Some would have us exercise entirely without apparatus or implements; others tell us that only by using the mechanical devices in which they are interested can we make true progress.

In Missouri, a State which will ever be famous as the home of Osteopathy, a sect of dirt-eaters has been started, and we are told that two hundred and fifty students in the State University there have pledged themselves to eat only twice daily for the next four months. A college trainer last fall forbade the members of the football team to wash in fresh water, forcing them to perform all their ablutions in salt water; and so it goes; I might, by a little research, indefinitely prolong this somewhat grotesque list of more or less peculiar performances, which are at present vaunted as conducive, if not absolutely essential, to health and long life. The above list, while incomplete and fragmentary, serves to illustrate the point which I wish to make, viz., that there is to-day a great and constantly spreading interest in all matters relating to the education and care of the body. Our colleges spent last year in sports over $1,000,000. At Harvard $250,000 is to be spent for a stadium, from the seats of which athletic games shall be witnessed by about 40,000 people, while the president of the university makes his annual plea in vain for a suitable building in which to house adequately and make available the books now in the college library. In spite of the protests of a large part of the medical profession, of the so-called leaders of thought, and of many clergymen, professors, and thinkers, the love of athletic sports increases day by day. How many learned opinions have I read in various publications, lay and medical, about the evil effects immediate and remote which must follow muscular development, as surely, if not as speedily, as night follows day.

Sir Benjamin Ward Richardson, an English medical writer of some note, said a few years ago that he did not believe that there was living in England at that time a professional or celebrated amateur athlete over fifty years of age who did not present symptoms of heart disease. Many of us can remember a novel by Wilkie Collins called "Man and Wife," written in great measure at least to decry the then increasing love of athletic sports in Great Britain. The late Senator Evarts is said to have attributed his long continued good health to the fact that he never took exercise. There used also to be a great deal said about the brutalizing tendencies of athletic sports. I remember my own father, after giving a reluctant consent to my rowing in a crew when in college, adding the admonition that I should not, if I rowed, allow myself to become a rowdy. Rowing men are not rowdies and athletic training teaches self-command and moderation rather than otherwise. How well I remember the words of a celebrated Boston surgeon of a generation ago, who told his son that rowing in races would surely lead to heart disease. This young man took little or no exercise in college, while his chum was in the university crew. Shortly after graduation from college, the former pricked his finger in the dissecting room and died of blood poisoning in a few days; whereas the rowing man is now alive and in good health, and has practised medicine for nearly thirty years. I might add that the brother of the first mentioned young man was a foot-ball player in college, and is now alive and well.

There have been unfortunately too few observations upon the subsequent careers of university crew men, and it has been easy for medical writers, in discussing the subject, of the effect of exercise on the heart, to fall into that spirit said by Huxley to be engendered by the habit of speaking without the expectation of a reply.

Of course there are writers and speakers of considerable power and acumen who take the attitude that if the facts do not fit their theories, it is so much the worse for the facts. And there is also a habit of the medical mind to forbid all practices of the safety of which there can be a reasonable doubt, so that it is easier to say do not do that, it may hurt you in after years if not immediately, than to say candidly I do not know what the effect of severe exercise will be upon the heart. Fortunately a number of accurate observations have recently been made upon rowing men during training, and immediately after the races, and now G. L. Meylan reports the results of an investigation of the subsequent health of one hundred and fifty-two Harvard oarsmen who rowed in boat races from 1852–1892. He chose oarsmen for investigation, inasmuch as there can be no question of the severity of the exercise and its liability to produce immediate or remote effects upon the heart, if any exercise can. His observations coincided with those of Dr. Morgan, published in England in 1873. This gentleman followed up two hundred and ninety-four Oxford and Cambridge oarsmen who rowed in University races in the forty years from 1829–69. All this testimony shows that severe training and rowing four-mile races does not produce heart disease, nor any other form of disease, and that oarsmen live longer and are happier, healthier, and the fathers of larger families than other educated men generally. And Meylan's investigation shows that a larger percentage of these oarsmen have attained distinction in letters and in the learned professions than college graduates who did not row.

It shows that of the college graduates whose names appear in "Who's Who in America," of the average graduate the percentage is 2.1; of the Phi Beta Kappa men it is 5.9, and of the oarsmen it is 8.3.

It is now up to these gentlemen who have said such sweeping things about the injury which severe exercise in general, and rowing in particular, may inflict upon the health, to produce some trustworthy evidence in refutation of Dr. Morgan and Mr. Meylan, or to confess, what the writer has all the time suspected, that they were going to their imagination for their facts, or relying upon hearsay and unverified evidence in support of their preconceived notions.

The observations of Dr. Morgan and Mr. Meylan must be very comforting to many anxious parents, who cannot keep their sons out of the college crews, as well as to numerous writers and thinkers, who have the welfare of their race at heart. For truly one might as well try to make water run up hill as to try to stem the present rage for athletics.

A brilliant writer said to me the other day, that the world seems to be reverting to the old Grecian love of physical prowess and admiration for the body beautiful. Of course, we are a long way from this yet. Fancy our hollow-chested, pigeon-toed women with their square hips and hour-glass waists dressed as the Greeks used to dress. Fancy our average business man with his protuberant paunch

and skinny arms posing as a Greek hero. Sad as this thought is, there is room for encouragement. Our people, both men and women, are improving in size, figure and carriage, and will continue to improve. Whether the general intelligence and mental development will ever reach as high an average among us as it did among the Athenians, is quite another question.

The great truth cannot much longer be kept from the man of average intelligence and education, that the condition of the general health is all important, and the special diseased conditions are the exception and are frequently the result of preventable causes; and that in the majority of cases, when a man is sick, the doctor can do him no good except with advice, and that he must rely upon his own constitution and his general health to pull him through, if he is to get through.

The desire for strength, for bodily vigor and comeliness, is perfectly natural and is born in all men and women. As I have just said, it is impossible even were it desirable, to stop the present interest in all things athletic. On the other hand, now is the opportunity for the real lover of mankind to confer inestimable benefits upon the race by guiding and directing them in the way that they must walk, if they would attain real physical excellence.

First, and most important of all, is to instil into the receptive mind of the child the physical conscience. He must be taught that it is just as wicked to injure his health or to deprive his body of its needed rest, recreation and exercise, as it is to steal, or lie to commit any sin. The sins against chastity, so disgustingly and alarmingly common, are also sins against the body, not only because of the immense risk of contracting venereal disease, but chiefly because no high-minded man, who truly respected his body, would be guilty of such baseness.

The medical profession must take stronger ground and be more outspoken against fornication, against alcoholic drinks, against tobacco, against confectionery, against gluttony, sloth and weak self-indulgence—in fact, against all the physiological sins which are daily and hourly committed in every part of this broad land—in the palace of the rich, in the hovel of the poor. But our duty is not done when we have forbidden all these injurious things, we must enjoin the physical exercises and the rules of correct living, without which, the body cannot be built up.

It is a great misfortune that the injunctions in the Scriptures to keep our bodies in subjection and mortify the lusts of the flesh, etc., should have been interpreted to refer to all bodily pleasure, and practically to all physical exercise and recreation. I submit that we are commanded to restrain our appetites, to curb our lust and contend with that craving for stimulants and narcotics which is born in every man, but it is inconceivable that we are not enjoined to educate and develop our physical powers *pari passu* with our minds, and our morals, if we wish to accomplish the moiety of the work in this world of which the properly developed man is capable.

There is absolutely no attribute or power of the human being, mental or physical, which does not need development and exercise and prolonged use before it can come anywhere near perfection. As M. Georges Demeny says, "The essential of physical education is voluntary motion." Massage, rubbing, etc., are at best only substitutes for voluntary exercise of the muscles. President Faunce of Brown University has said, in speaking of the "advantages of disadvantage," that college boys take up athletics to compensate themselves for not having been brought up to work on a farm. In other words, not having previously enjoyed an opportunity to acquire the physical basis necessary for years of mental work and nervous strain; they take to athletic sports in college with great avidity, and according to the learned gentleman just quoted, in a measure make up for their bodily deficiencies in this way.

You may tell me that certain men have achieved greatness in spite of feeble and ill-developed bodies. While this may be true in some cases, it is not generally so. So far as known, the world's leaders have, generally speaking, been of powerful physique, and have also been men of simple tastes and abstemious lives.

It has even been asserted that no man in this country has risen to eminence in either the medical or legal profession who has not at some time in his life worked with his hands. I may be met by the objection that strong and muscular men need much physical exercise to keep their robust frames in good condition, and that professional men cannot spare the time for this. This objection is more apparent than real, because all men whether muscular or not, need some exercise to keep them well, and fifteen minutes hard exercise in the morning beside the cold bath, that every gentleman is supposed to take, is enough to keep a stalwart body in good health. Always provided, that the diet is strictly limited and the man leads a correct life in other respects.

Whatever view of the spiritual life of man one may take, a moment's reflection will show that healthy and vigorous thinking cannot go on in a diseased brain, nor in an improperly nourished brain, nor in the brain of an overfed man. Every one knows that if he eats too heartily he cannot think clearly for some hours afterward, and he also knows, if he has watched men at all, that inordinate feeders, not to mention drinkers, are of apathetic minds and slothful bodies. Whether the brain is a dwelling place for the soul, or whether it is a secreting organ, and "secretes thought as the liver secretes bile," there can be no question that it must be healthy and well-developed, and a part of a healthy and well-developed body, in order to do its best work.

All life, as it manifests itself to our senses, is characterized by action, growth, recession, and decay. There is never-ceasing change so long as life lasts. It is also evident that under varying conditions, plants and animals develop in ever-varying ways, so man grows, reaches maturity, decays mentally and physically, and dies. Is it reasonable to assume that his complex and wonderfully formed body can grow up and develop itself properly without thought or care, on its owner's part?

No one disputes with a cattle-raiser or a horse-breeder, or even a chicken raiser, about the advantage, in fact the necessity, for applying the best and most recent scientific knowledge to the development and care of his charges. Even chicken fanciers make their poultry exercise during the winter by hanging their food nearly out of their reach, so that the chickens must jump for it; or burying it under leaves or straw, so that they must scratch for it. And shall we not make a more thorough study of the health and well-being of the human animal? Herbert Spencer says, "The raising of first-rate bullocks is an occupation, on which men of education willingly spend much time, inquiry, and thought; the bringing up of fine human beings is an occupation tacitly voted unworthy of their attention." However, history repeats itself, while the leaders of thought have disdained to busy themselves with the proper nurture and development of the human body, the natural instinctive love of strength and bodily vigor which is born in every Anglo-Saxon breast has reasserted itself, and, as I said before, the interest in

everything pertaining to bodily development grows apace. And has grown and spread mightily during the recollection of men yet young.

I should not like to leave this subject without a few more words upon the mental aspect of education in its relation to the physical. I say without hesitation that the body cannot and will not reach the highest state of physical health unless its mental powers be also developed.

This paper is a plea for a symmetrical bodily and mental development. Many men will acknowledge that for the best mental health a strong and vigorous body is needed, but I doubt whether it is generally appreciated that for the best physical health a clear and well-educated mind is essential. In fact, we speak of mental and physical health as though they were two distinct states, capable of existing separately. Nothing can be more erroneous. Health is the normal condition of bodily and mental vigor, which every human being should possess, and it is as absurd to speak of an insane person as being healthy as to say that Stevenson was healthy when dying of consumption, although his magnificent intellect was apparently still undimmed.

We have Sandow's authority for the statement that one cannot develop a muscle or set of muscles without concentrating his mind upon those muscles. He says that "It (physical development) is the mind. All a matter of the mind, the muscles really have a secondary place;" and again . . . "A man with strong concentration of mind will develop quicker in the quality of his muscles, than will he who cannot concentrate his mind upon the matter."

And these statements I believe to be true. I believe also that the bodily and mental powers are so interdependent and so indissolubly joined, that neither can be exclusively developed without injury to both. The body is not only a highly complex machine, it is a growing, developing, ceaselessly changing, living entity. If a locomotive is so constructed that the boiler will generate more steam than the steam box can hold, there will be an explosion as soon as there is a strain put upon the machine; and if the boiler, the cylinders, and the steam boxes are remarkably strong, while other parts of the machinery are weak, there will soon be a breakdown and the engine will spend most of its time in the repair shop.

In this last condition is the highly educated man who has neglected his body. He has brains, but not brawn, and while he is capable of much good work, he cannot endure prolonged effort, nor the constant hammering which is necessary to achieve anything really worth while, half so well as he might have done had he more bodily vigor. But suppose in our locomotive that the running gear is all right and every part of the machinery of the first class, except the boiler, no pressure of steam can be generated, and the fine and complex machine is comparatively useless. In this state is the man with the great muscular development, who lacks in mental force and application. The stupid and brutal prize fighter, without any book knowledge, is as much of a *lusus naturæ*, a mistake and the result of one-sided training as the college honor man who breaks down about the time he takes his degree, or shortly afterward; or the neurasthenic college woman, who divides her time between reading Ibsen and languishing on a couch. Perhaps there is no more striking illustration of the want of mental balance which comes in many cases, at least from a want of bodily development, than the hysterics of the popular preacher. How much more real good would these men accomplish, if their fervor were tempered with moderation, and their zeal with that sane and rational frame of mind, that patience, courage, and self command which hard and long trials of strength and skill engender, and which we especially note in men of deep chests and stalwart muscles. Not in men like the "lean and hungry Cassius, who could not sleep o' nights."

We want the all around man who does not disdain a good meal and pleasant society, a man who likes, in moderation, pleasure and sport; in short, a well-balanced man who works hard, plays hard, lives moderately, sleeps soundly, and is, in short, *fortiter in re suaviter in modo*. A man who heeds the dictates of his moral and his physical conscience, who lets neither his mind nor his body deteriorate prematurely by disuse on the one hand, or ill-judged over-exertion or weak self-indulgence on the other. Who is honest with himself and cultivates a spirit of charity toward mankind and reverence toward his Maker. Only in such men do we find the cheerfulness and contentment which come from work well done. The poise of spirits, the serenity of a well acting mind, and the subjugation and regulation of the bodily instincts and passions, which are necessary to a well-ordered manhood and a serene old age.

How often do we note nowadays in both men and women, a condition of mental dyspepsia due to improper mental pabulum, to overfeeding the mind with fiction and sensational literature; which shows itself in the all too prevalent disordered fancies and silly theories, which the half-educated call wisdom. There is a lamentable lack of a true sense of proportion in the mental attitude of many teachers and writers, partly due, I think, to their own ill-developed or pampered bodies.

It is a common saying of the day that educators and clergymen are as a class lacking in judgment. It is they who support and sympathize with the quack and the irregular practitioner. It is they who mistake hysteria for piety, effrontery for skill, and a flattering tongue for true learning.

In closing, let me put in one word the great truth this paper is meant to inculcate.

Struggle as we may against it, the conclusion is unavoidable that work, steady, regular, persistent work, both mental and physical, is necessary for the average man; without it, he will not only not accomplish anything of value, but he will be miserable, because while he may not be able to appreciate the reason he will be abundantly sensible of the fact that he is a failure.

Only the workers have tasted the sweets of living. They have been happy because they have

"Girded their spirits and deepened the streams
That make glad the fair City of God."

Our bodies, our mental faculties, our special senses are all tools with which the indomitable spirit works. These tools may be rough, badly forged, and badly tempered, or they may be even, smooth, well forged, and exquisitely polished; with which think you will the best and most enduring work be accomplished?

Concerning the Practical Value of Recto-Romanoscopy—S. Kelen discusses the value of the rectoscope recently introduced by Strauss, in which the examination of the rectum is simplified by inflating that organ and the sigmoid flexure with air. The method is particularly effective in ascertaining the condition of the rectum at higher levels than those brought into view by the ordinary instruments, and the author claims that it is possible to make a diagnosis of lesions in the ampullæ or the beginning of the sigmoid flexure. He has also been convinced that the rectal tube introduced for the purpose of giving a high enema does not pass beyond the ampullæ, and suggests that the tube be introduced through this instrument after the latter has been inserted about 25 c.c. and the lamp removed. In this way the liquid is certain to get into the sigmoid flexure.—*Pester medizinisch-chirurgische Presse.*

A STUDY OF INTESTINAL PERFORATION AND PERITONITIS IN TYPHOID FEVER, WITH A REPORT OF THREE SUCCESSFUL OPERATIONS, AND A STATISTICAL INVESTIGATION OF 295 OPERATIVE CASES.*

By WILLIAM D. HAGGARD, M.D.,
NASHVILLE, TENN.

PROFESSOR OF GYNECOLOGY, MEDICAL DEPARTMENT, UNIVERSITY OF TENNESSEE; FORMERLY PROFESSOR OF GYNECOLOGY AND ABDOMINAL SURGERY, UNIVERSITY OF THE SOUTH; GYNECOLOGIST TO THE NASHVILLE HOSPITAL; FELLOW OF THE SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION; MEMBER OF THE WOMAN'S HOSPITAL SOCIETY OF NEW YORK, ETC.

THE immortal phrase "The resources of surgery are rarely successful when practised on the dying" has been most wonderfully negatived in the operative treatment of perforative peritonitis in typhoid fever. Surgery has reclaimed many otherwise irremediable conditions. It was a great step when Sims suggested abdominal section for intestinal perforation for gunshot wounds, which daily rescues many victims. It was a great step when Fitz and McBurney taught us the frequency and means of relief of perforation of the appendix, which has saved so many valuable lives. But it is a still greater achievement to be able to succor the hopeless sufferer from the onslaught of a fatal peritonitis from perforation in typhoid fever.

The possibilities of this latter achievement, however, have not yet been appreciated keenly enough by the profession. It is almost a score of years since Mikulicz did his first operation in 1884. Since that time, I am only able to collect, from all sources, by the most diligent search through the literature, together with cases personally communicated, 295 cases that have been subjected to operation up to May 1, 1903. Granting that there have been as many, or twice as many, cases that have not been reported or found, I still claim that the total sum is pitiably meagre. For we have only to reflect that an estimate of 500,000 cases a year occur in this country alone, and with a general death rate of 10 per cent. to 15 per cent., 50,000 or 75,000 souls perish annually from this terrible scourge which we daily implore families and municipalities to prevent.

Osler says that one-third of the deaths from typhoid fever are due to intestinal perforation. Taylor thus estimates that 25,000 deaths occur yearly from this accident. On the basis of a possible 30 per cent. recovery by operative interference, he further concludes that 7,500 persons perish in the United States each year who might be saved.

The reasons for this are complex. They are partly preventable, and partly irremediable at this time. One explanation is the reluctance with which the practitioner invokes the aid of surgery in the presence of such forbidding general symptoms. Another is the likelihood of death even with the operation; but the greatest of all is the great difficulty of making a positive diagnosis in the early stages. This difficulty will always exist with our present methods of diagnosis. It may be considerably lessened by a proper appreciation of even the suspicious abdominal symptoms, intelligent alertness, and frequent examination.

Perhaps the greatest stumbling-block is the classical picture of perforation which needs erasing: the drawn, pinched features, pointed nose, profuse sweat, cold extremities, rapid, feeble pulse, short, sighing respiration, distended and motionlesss abdomen, restlessness and delirium—these are the late and lethal manifestations of peritonitis, and not of perforation.

I regret that we have not as characteristic a picture of the early symptoms of perforation. Some cases are fairly typical, but others presenting such presumably typical symptoms are found not to have perforation. Again, peritonitis may be the first symptom. Given a man in the third week of a mild attack, without abdominal symptoms and pursuing a regular course, who is suddenly seized with an acute, paroxysmal pain in the right lower quadrant of the abdomen, that causes him to cry out, that is unrelieved by ordinary measures, followed by collapse, subnormal temperature and rapid pulse, which are succeeded by a rise in temperature in a few hours, associated with continued pain, considerable tenderness and right-sided rigidity, together with a rapidly increasing leucocytosis, the diagnosis of intestinal perforation is reasonably certain—not absolutely—but surgically. All such cases should be operated on as quickly as possible.

The difficulty is that all cases do not present this typical grouping.

No abdominal symptoms, objective or subjective, occurring in typhoid fever, should be considered trivial. Pain is usually the first note of alarm.

My study of the reported cases develops that a sudden severe colicky pain is present in a large majority of cases. Collapse is an infrequent attendant of perforation, and was present in only about 6 or 7 per cent. Fall in temperature was not constant, but rise in pulse was rather uniform. Of the physical signs, tenderness (sensitiveness) was found to be the most constant. And studied in the order of their development, and more especially their significance, it was found that pain, then tenderness, then rigidity, and then localization in one spot occurred.

Persistence of symptoms serves to distinguish them from colic which should disappear in a few hours or change its location.

Recognizing the difficulties and limitations in diagnosis, exploratory incision should be regarded as a necessary and final aid in diagnosis.

The facts about intestinal perforation, which I have deduced from a statistical study of the cases, may be summarized as follows:

1. It occurs more often in men than women—80.9 *vs.* 19.1 per cent. It is, like hemorrhage, rare in children.

2. It occurs in about 2.5 per cent. of all cases of typhoid fever.

3. 3.31 per cent. occur in the first week; 20.19 per cent. in second week; 38.94 per cent. in third week; 14.90 per cent. in fourth week; 9.13 per cent. in fifth week; 5.75 per cent. in sixth week; 7.21 per cent. from seventh to eleventh week, and has been observed as late as the one hundredth day (Curschmann). Holmes operated on one case after four months.

4. It naturally occurs more frequently in severe attacks, but may occur in mild attacks, and it may be the first real symptom of so-called walking typhoid.

5. It occurs in the ileum in 95.5 per cent., usually in 18 inches of cæcum (Osler), always in 3 feet (Loison). In the large intestine in 12.9 per cent., and is most often situated in the ascending, transverse, and descending colon, sigmoid and rectum, in the order named. It may occur, also, in the appendix, Meckel's diverticulum, and jejunum.

6. The perforation is single in 84 per cent. There may be two or more, and in one case there were twenty-five (postmortem). Cases with diarrhœa and tympany are more likely to have perforation. Six out of thirty cases occurred with hemorrhage. (Osler.)

7. The death rate given by Murchison is 90 per cent. to 95 per cent. Osler says he could not recall a

*Read before the American Association of Obstetricians and Gynecologists, Chicago.

single case in his experience that had recovered after perforation had occurred.

Occasionally the careful observer and conscientious surgeon, in his earnest effort to interpret signs aright, and to operate before general peritonitis has rendered the patient hopeless, may open the abdomen to find no lesion whatever. This has been done by the most expert, and will sometimes happen until we devise some absolutely early sign. Commonly the patients progress and get well, as though nothing had been done to them. It has demonstrated the fact that these patients will bear the surgery necessary to make a positive diagnosis in suspected, but doubtful cases. Indeed Finney advises exploratory laparotomy under cocaine anæsthesia in suspected cases. To be sure, there is some chagrin attaching to a seemingly unnecessary operation, but it is much better to do such an operation upon a mistaken diagnosis, than to neglect to do it upon a case that demands it.

To avoid this embarrassment Connell has ingeniously devised recently a procedure based upon the fact that sulphuretted hydrogen will, when passed through a solution of acetate of lead, turn it black by the formation of sulphide of lead. He proposes, as the result of animal experimentation, to introduce an ordinary trocar and cannula into the lower part of the abdomen in suspected cases of intestinal perforation, to insufflate filtered air, which, mixing with the intestinal gas in the peritoneal cavity, is allowed to escape through another cannula at the upper part of the abdomen, into a solution of acetate of lead. If sulphuretted hydrogen be present as a result of a perforation, the reaction will take place.

Other experiments were made by injecting sterile salt solution, and withdrawing it in from three to twelve hours. Where the intestine had been intentionally punctured or opened, and the salt solution allowed to mix with the fecal extravasation, when it was withdrawn, ammonia could be detected by Nessler's reagent, indol by sodium nitrate and sulphuric acid and proteoses by the biuret test.

None of these tests were positive in air or fluid injected and recovered from the normal peritoneal cavity. The method appears to be harmless, but lacks additional confirmation as to its uniformity and reliability. Meanwhile the diagnosis of perforation must rest upon the minutest scrutiny of suspicious signs, which, if deemed reasonably certain, should demand an exploration; or upon the advent of peritonitis, it should be imperative. The mild and early symptoms are the important ones. The severe symptoms usually mean peritonitis.

t is surgically immaterial whether a perforation exists or not if there is peritonitis. It is more apt to be localized if there is no great extravasation. Peritonitis in typhoid fever may be due to migration of bacteria through the intestinal walls without actual perforation, as evidenced by the number of cases of peritonitis without perforation. It may result from ruptured abscess of the liver, rupture of the spleen, or of the gall-bladder or ducts, of the mesenteric glands, appendix, and from gangrene of the intestine caused by thrombosis.

The surgeon should stand in close relationship with the physician in typhoid fever, as is now the quite general custom in appendicitis. Cushing advises that he should be consulted at the first indication of a localized peritonitis, and should perforation and extravasation occur, operation may be undertaken without delay. Osler advises—"In doubtful cases patients should be given the benefit of the doubt and operation urged (*The Lancet*, February 9, 1901). Keen says "We should operate in practically every case of perforation, unless the condition is such that recovery is evidently hopeless." (*Journal of the American Medical Association*, January 20, 1900.) Further, "after perforation has occurred operation should be done at the earliest possible moment, provided that we wait till the primary shock, if any be present, has subsided."

Case I.—My first case was in 1898, and reported in the Transaction of the Southern Surgical and Gynecological Association, 1899. Woman, nineteen years of age, married eight months. In the third week of severe typhoid fever with delirium, a tender swelling developed in the right iliac region, that was quite frank and prominent. When I incised it, the gas and pus were forcibly ejected from the tension in the sac. It was larger than a cocoanut, and well walled off. The cavity healed in about three weeks. The fever progressed with increasing severity and she died from toxæmia, three and a half weeks after operation in the seventh week of the disease. Widal's test positive. No autopsy. This case is very similar to case 122, in Keen's list, reported by Munro, which is recorded as a surgical recovery.

Case II.—July, 1901. Boy, nine years of age with mild typhoid fever, with some tenderness and slight rigidity in the right iliac region that inclined us to diagnosis of appendicitis. On the nineteenth day he developed symptoms of localized peritonitis in the right iliac region. Incision over the slightly dull tumor at my clinic at the University of the South revealed a fairly well walled-off area, the walls of which were almost in apposition, the sides and bottom of which presented three perforations; two appeared to be in the inner wall, composed of small bowel, and one in the outer wall or colon; no pus but a slight amount of fecal fluid. All of these openings were sutured and drainage established. A fecal fistula appeared on the third day and persisted. He remained in bed with typhoid symptoms and temperature for ten weeks, and developed a left suppurating parotid. I closed the fistula eighteen months afterward with success.

These two cases were examples of the two types of local peritonitis: perforation with abscess formation and perforation with walling-off by adhesive peritonitis, the perforation still patent.

Case III.—Example of free perforation. Male, aged thirty-four, in previous good health. He was under the care of Dr. Sugg of Beachville, Tenn. On October 8, 1903 (the twelfth day of the disease), the temperature was 101°, instead of 100° as usual; the pulse 92 instead of 72 or 80. An enema was given, which acted well. At 11 o'clock the patient was seized with sudden, severe colicky, abdominal pain. The pain abated somewhat, and when the doctor reached him the temperature was normal and pulse 72. An enema was ordered and a turpentine stupe applied. At this time there was little or no tympanitis, nor had there been in the entire progress of the case. At 2 P.M.—three hours after the onset of pain—the patient was still suffering with considerable abdominal pain. There was slight tenderness over the abdomen, which was most pronounced in the right lower quadrant, extending a trifle to the left of the median line. There was slight abdominal distension. The temperature had risen to 104° and pulse was 120. The face was anxious and apprehensive.

Dr. Sugg made the diagnosis of perforation. The patient was ten miles in the country, and I reached him seven and one-half hours after the onset of pain. The conditions were unchanged, except that the temperature had receded to 102.6° and the pulse was 116. The sudden onset of acute abdominal pain in the second week of a mild case of typhoid fever, followed

by rapid rise in temperature and pulse-rate, the anxious facies, the undiminished pain, the distention, tenderness, and rigidity indicative of beginning peritonitis, pointed quite strongly to perforation. Although it was after night-fall, in a three-room farm house, with no facilities for operating, yet in the face of an otherwise fatal issue, and with the patient's consent, preparations were made as rapidly and completely as possible, and abdominal section was made eight and one-half hours after the onset of pain. When the peritoneum was opened in the right semilunaris, a quantity of free, odorless, chyme-like, yellow fluid made its escape. The cæcum was at once located and pulled up with the appendix for inspection. The latter was found to be normal. The adjacent ileum was deeply injected and presented a modena-color, and was slimy from being bathed in the pea-soup effusion. It was passed between the fingers for a few inches, and at about twelve inches from the cæcal extremity the perforation was found. The actual opening was small and situated in the center of an indurated area about as large as a five-cent piece. Upon manipulation there exuded from the perforation yellowish intestinal contents corresponding in color and odorlessness to the free fluid found in the cavity. The knuckle of gut containing the perforation was surrounded by gauze pads, and the indurated area containing it was inverted by five Lembert sutures of small silk. A second layer was placed above and between the first row and at the angles.

The sutured area was temporarily surrounded with gauze and replaced in the cavity pending the peritoneal toilet. As much of the pea-soup material as possible was sponged out of the right iliac fossa and the pelvis, and then the cavity was filled with salt solution poured from a pitcher. The small quantity that was prepared in the limited time was exhausted before the cavity was at all clean, and here came the greatest technical difficulty of the operation. There was an abundance of boiling water, but no cool boiled water. A by-stander was sent to the spring with a clean pitcher for water which had to be dipped up, this delayed us some minutes. I thought the unsterilized water was less harmful than the known septic fluid. The irrigation was satisfactorily completed, and the patient turned on his side and all fluid allowed to run out. The gauze around the injured intestine was replaced by two clean gauze strips which met under the perforation, and were so disposed as to bring that portion just under the incision. A gauze strip was introduced into the bottom of the pelvis, and another in the right flank, and the wound closed by interrupted worm-gut sutures. The entire operation comprised thirty-eight minutes, including the delay.

The pulse at completion was 96, and not above 84 on the following day. The temperature did not exceed 100.8°. On the second night the temperature reached 102°, and the pulse, after the excitement of being told of his serious condition by his wife, went to 120. With that exception the pulse did not go above 108. The facies during the second night was anxious, the legs flexed, the respiration difficult, nausea was persistent and vomiting frequent and offensive. There was considerable distention and severe pain, requiring $\frac{1}{8}$ gr. morphine, with marked subsidence of the symptoms. Flatus was passed in considerable quantity toward morning and the patient was more comfortable, but the mind was not clear. The gauze was removed in forty hours, being loosened by hot salt solution introduced by a glass catheter, which was allowed to run into the abdomen until it came back clear. The bowels moved well after this, and the case progressed satisfactorily with a morning remission to 100° and an evening exacerbation to 101°, pulse varying from 84 to 96.

On the twenty-second day of the fever and the tenth day after operation the temperature remained normal for two days and the stools appeared normal. On the twenty-fourth day he had a relapse, the temperature reaching 102.6° and the pulse 108. The tympany returned, rose-spots again appeared on the chest and abdomen, and the stools became loose and offensive. Defervescence occurred in the fifth week, the temperature returning to normal, and the belly became scaphoid. The patient became brighter and hungry. He was again considered convalescent, but after three days of convalescence he became somnolent and listless; the urine diminished in quantity and was found to contain albumin in considerable quantity. He was greatly weakened, but was able to leave his bed in the eighth week and has remained well since.

Technique.—Inasmuch as the usual site is near the ileocæcal valve the right iliac incision should be chosen. In cases of general peritonitis a central incision is better. The ulcer when found, may be trimmed or excised, or simple invertion suture seems to be competent. The mattress suture has the advantage of only one knot for two threads. The second row may be continuous to save time, and a third may be added if it does not constrict the lumen too much. Sutures may be transverse or longitudinal. Care should be taken not to cut off too much of the circulation when the ulcer is situated near the mesentery.

The Cargile membrane is recommended for additional protection. Search should be made for other perforations and any thinned areas inverted by suture. Resection may be practised if there is much destruction, but the formation of an artificial anus is best in the majority of cases in greatly debilitated subjects. Escher saved three out of four cases by ileostomy. Copious irrigation is essential in extravasation or general peritonitis. Sponging out is better in localized and walled-off areas.

Drainage by the vagina is preferable in women. Lumbar punctures and drainage by tube and gauze is expedient in men. Most of the wound may be left open with advantage and the damaged area cofferdammed with gauze and located very near the incision. To facilitate drainage and localize infection in the less vulnerable pelvic peritoneum, instead of the fatally absorptive diaphragmatic area, Fowler advocates sitting the patient up at an angle of 40 degrees. Murphy reported six cases—consecutive—of general peritonitis (one typhoid) in which recovery followed when this was done. I have for some years been turning the drained cases of appendicitis on the right side from the start with this idea in view.

Statistics.

Westcott collected 83 cases in 1897 (published by Keen) with 16 recoveries, 19.36 per cent.

Tinker collected 75 cases in 1898 (published by Keen) with 21 recoveries, 26.66 per cent.

I have collected 137 cases (published and unpublished) with 43 recoveries, 31.31 per cent.

This makes a total of 295 cases, with 80 recoveries, 27.11 per cent.

Of this grand total only 246 were sufficiently complete for purpose of study. Of this number there were:

89 cases of free perforation, with 29 recoveries, 36 per cent.

19 cases of localized peritonitis, with 9 recoveries, 47.3 per cent.

138 cases of general peritonitis, with 29 recoveries, 21 per cent.

There were 16 cases at Johns Hopkins up to 1901, with 6 deaths, 37.5 per cent. Cushing had 11 cases with 5 recoveries, or 45.5 per cent. He predicts that

the percentage of recovery will soon be from 50 to 60 per cent.

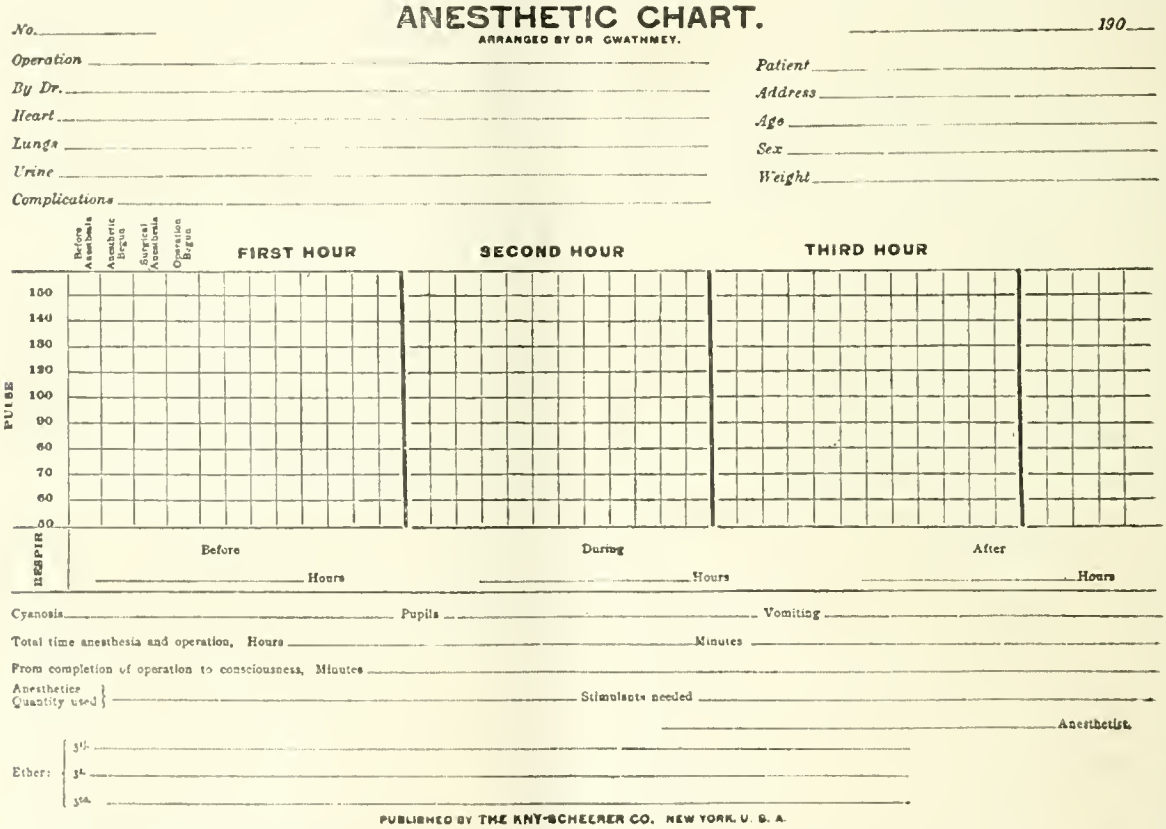
I feel that a saving of over 27 per cent. in all cases, good and bad, extending over a period of twenty years is a most encouraging showing, and that 36 per cent. in cases of free perforation should encourage us to a more prompt diagnosis and the invocation of surgical relief to these otherwise hopeless subjects.

A more general appreciation and application of the possibilities of operation for typhoid perforation will not only be a great surgical triumph, but will add many precious years to the span of human life.

IMPROVEMENTS IN ANÆSTHETIC APPARATUS AND TECHNIQUE.

By JAMES T. GWATHMEY M.D.,
NEW YORK.
ANÆSTHETIST TO GOUVERNEUR, NEW YORK SKIN AND CANCER, AND THE CITY HOSPITALS.

In a progressive science like that of anæsthetics we must constantly expect improvements. A few new ideas and methods that have been tried and found of value are herewith offered for what they may be worth. In order to facilitate the acquirement of more exact knowledge by everyone concerned, an anæsthetic chart should be in every hospital, regardless of the method or anæsthetic used.



The surgeon would thereby get more exact data on all cases, and the hospital interne be compelled to give closer attention to details. In all chloroform anæsthesias the pulse should be taken every five minutes, the time recorded at the top of the chart and the rate by a dot on its respective line. This should also apply to all chloroform mixtures, as the A. C. E. (alcohol 1 part, chloroform 2 parts, ether 3 parts) or C. E. (same as above with the alcohol left out). During ether narcosis, the pulse-taking would depend entirely upon the patient's condition and the nature of the operation, but, as a general rule, the pulse should be recorded as above. The charts are arranged in book form with a carbon sheet, so that one chart may either be placed on file (if a hospital case) or given to the surgeon, the other kept by the anæsthetist. The amounts given in similar cases for the same length of time, and by different methods, would also prove of inestimable value.

If the case is a difficult one for the anæsthetist, the pulse should be taken by the non-sterilized nurse. There are many other reasons for an anæsthetic chart in both public and private cases, but the above are sufficient.

That Junker's Inhaler is not more often used in our hospitals in operations about the head, is due, in the writer's opinion, almost entirely to the idea of giving chloroform through a closed inhaler and mask with valves. Take the margin of a German ether inhaler as a model for the face-piece, having this perforated with holes around the inner margin, and the rest of it made as an ordinary chloroform mask. Covering this with two layers of gauze, and using a two-ounce bottle with a stopper and catch (instead of a screw stopper), we have a very simple form of inhaler. If the small mask is found to be in the way, the metal tube may be substituted and used also as a retractor, the anæsthetizer thus becoming an assistant to the surgeon, instead of hampering him. I have used this inhaler in over fifty very difficult cases, most of them over three hours and two of them over four hours in duration. Several of these cases were athletic alcoholics, such as give most trouble to the anæsthetist, but it has never failed to give satisfaction. For extirpation of the tongue and similar operations where the surgeon prefers an analgesic rather than an anæsthetic state, when a cough or swallowing movement materially aids in clearing the throat, this level of narcosis can certainly be maintained by this method more easily than by the drop method.

The Gwathmey chloroform inhaler then (a modification of Junker's) consists of a two-ounce bottle with a metal tube running to the bottom, and connected on the outside with the afferent tube from the hand-bellows. The efferent metal tube simply perforates the rim of the bottle, and is connected with the mask by another rubber tube. The bottle is graduated to hold 8 drachms, which is usually

sufficient, although in the case of alcoholic subjects an extra 4 drachms should be added. On pressing the bulb, air is passed through the anæsthetic and the chloroform vapor carried to the mask by the efferent tube. If at the end of six minutes the patient is not unconscious, additional chloroform should be sprinkled upon the mask. While it is not the intention to go into details in an article of this kind, it may be well to state here that after the patient has become quite unconscious, "only small doses are required to maintain anæsthesia, as it is

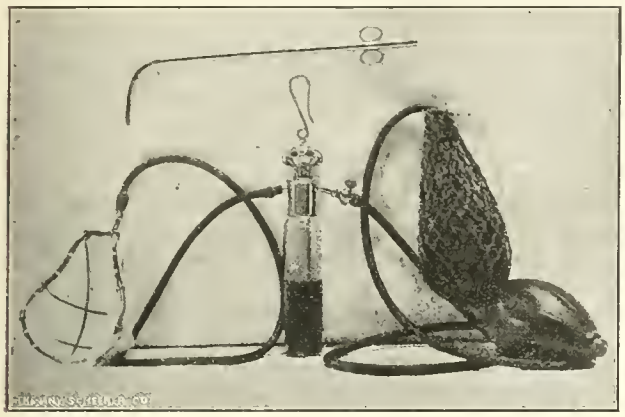


Fig. 1. The Gwathmey oxygen-chloroform inhaler.

necessary to introduce only so much further chloroform as is required to replace what is lost by exhalation, and thus to maintain in the blood that percentage of chloroform which at first was required to induce anæsthesia." (Luke.) A metal stop-cock has been placed on the efferent tube, and by turning this, the percentage of chloroform vapor can be easily regulated.

Whenever possible, the nitrous oxide-ether sequence should be used as a preliminary, the change to chloroform being cautiously begun with the

Fig. 2. Bulb on the floor—giving the anæsthetist the use of both hands.

return of the reflexes, such as a cough or swallowing movement. When the above method is used, "chloroform anæsthesia may be maintained with a risk to life which is so small as to compare very favorably with, if it does not actually reach, that of ether anæsthesia" (Hewitt). If at any time, the patient is troubled with shallow breathing, a few drops of ether on the mask will quickly remedy this condition. "Overdosage is less apt to occur with a Junker's Inhaler than with the drop bottle" (Blumfield). Many surgeons have recommended this method whenever chloroform is indicated. If it is necessary for the anæsthetist to keep the throat clear of blood, etc., during the operation in addition to maintaining the level of anæsthesia called for in order to have the use of both hands, he simply drops the bulb on the floor and makes the necessary pressure with either foot. The metal tube and mask are

Fig. 3. Combination gas-ether narcosis.

to be sterilized before and after every operation. If any chloroform is left in the bottle, it should be thrown away.

From experiments recently made by myself with this apparatus—using a closed inhaler—and killing between 50 and 100 cats. I can state that a mixture of oxygen and chloroform is three times as safe as one of air and chloroform and almost as safe as ether

Fig. 4. Combination oxygen-ether narcosis.

and air. Details regarding the results of these experiments will be given in a subsequent article.

Since the introduction of gas-ether inhalers into our hospitals, the criminal carelessness with which they are treated deserves attention. Because they are on the anæsthetist's table the surgical nurse or whoever may have charge of the instruments seems to think that it is unnecessary to give any more attention to them than to an ether or chloroform bottle. Doubtless many cases of pneumonia have

already been contracted from these septic inhalers. All the metal parts of the inhaler should be boiled, and all rubber parts should be treated with a carbolic solution, 1-20, and dried carefully. They should not be put together until the anæsthetist is ready to use them again. In all operations where the anæsthetist may come in contact with the surgeon or his instruments, the inhaler and all instruments of the anæsthetist should be sterilized, a sterilized towel should be placed over the anæsthetist's table and sterilized gauze wrapped around the chloroform bottle and ether can. If the above is carried out, the anæsthetist may with propriety "wash up" and put on white sterilized gloves, but otherwise it is nonsense.

As the valves of the Gwathmey gas-ether inhaler are absolutely independent of each other, two combinations are possible with this inhaler, that cannot be given with any other. With the ether chamber turned on full, and the expiratory valve on the face-piece open, keeping the gas-bag connected with the gas tank and maintaining a positive pressure in the bag, thus allowing the gas to flow through the ether chamber, a very satisfactory combination gas and ether narcosis can be given. At every third or fifth breath remove the mask and allow an intake of fresh air. A soft, easy breathing, with a slow pulse, is thus secured and maintained. This anæsthetic is indicated where for any reason it is desired to abolish the reflexes and yet give as little ether as possible. By this method a deeper anæsthetic than gas and air or gas and oxygen is secured, but not as deep as ether alone. The cases must be selected—middle-aged women and feeble men can be easily carried several hours. Athletes and alcoholics will not take it so readily. It requires close attention, for as soon as the mask is removed, the patient recovers, and if properly given there will be no nausea or vomiting. ℥xxx of ether every five minutes is usually sufficient.

The combination of oxygen and chloroform has been given thousands of times by placing a tube from the oxygen tank under any ether mask, but this means unknown quantities of both oxygen and ether. By allowing the oxygen to flow continuously through the ether chamber (as in the gas and ether combination) the oxygen carries with it the ether fumes. This anæsthetic is indicated in all conditions of shock and collapse. I have given this for over one hour and a half to a patient with intestinal perforation. The radial pulse could not be felt at any time before or during the operation, but the pulse continued good, and the general condition was better after the operation than before. In ordinary cases the pulse will go as high as 115 or 120 with the commencement of oxygen, but will drop back again to normal in five to ten minutes, and so remain.

For the tri-sequence, one should use the gas-ether sequence as a preliminary, and then ether in the usual way. If the operation lasts over two hours, continue the anæsthetic as in the gas-ether combination. In other words, in all long operations the last part should be more of a gas than of an ether anæsthesia. By this method the patient is thoroughly conscious at the end of the operation, and there is always less nausea and vomiting.

Too little attention has been paid to this sometimes most distressing part of an operation. A prominent surgeon said, "The only way to prevent this, is to cut the patient's head off." But in over 90 per cent. of all cases this condition can be prevented by the observance of the following well-known but usually neglected rules: (1) Keep an open-air way at all times (not an easy thing) by keeping the head to one side and the jaw pressed well forward. (2) As soon as the anæsthetic is removed, replace the ether odor by any other stronger smell, salts or cologne (if not too sweet). This is on the theory that the olfactory nerve is largely responsible for at least the initial symptoms, and results would seem to indicate that this is correct. More than merely "not to kill the patient" is demanded of the anæsthetist of to-day. Close attention to technique and nicety in every detail have elevated anæsthetization to the place it now holds.

124 East Sixteenth Street.

HAY-FEVER, SOME PRACTICAL SUGGESTIONS AS TO ITS MANAGEMENT AND TREATMENT.

By RALPH WAIT PARSONS, M.D.,
OSSINING, N. Y.

Of the many diseases to which man is heir, few are more intractable, and as regards the results of treatment, few more unsatisfactory, than the condition commonly known as hay-fever. Particularly is this the case when the patient either declines, or is unable to avail himself of the services of a physician who is skilled in the treatment of the diseases of the nose and throat.

Some patients with hay-fever do not experience much inconvenience from their malady; but, in a large number, the discomfort and actual suffering are so great as seriously to interfere, at times, with their business pursuits and social enjoyment.

Hay-fever being essentially a chronic affection, time and patience are important elements in the treatment of the disease.

I feel confident that if the hygienic and therapeutic measures herein advocated are adopted, many patients suffering from hay-fever will find considerable relief from the annoying symptoms of the disease, and some will be permanently cured. The patients should be urged to carry out the physician's directions carefully and systematically, in order that the best results of treatment may be obtained.

A few words as to the predisposing causes of the disease. It is generally conceded that there are three conditions which are necessary for the production of hay-fever, namely: (1) An irritant to the nasal mucous membrane, such as pollen, dust, etc.; (2) a neurotic habit; (3) an obstructive lesion in the nose.

It is not my intention in this paper to enter into the discussion of the pathology or symptomatology of hay-fever. These have been so thoroughly described in textbooks on the diseases of the throat and nose, and especially in the admirable work of Dr. Bosworth, that we need not dwell upon this branch of the subject. Suffice it to say that Dr. Bosworth lays stress upon the fact that he considers hay-fever as being due to a vasomotor paresis of the walls of the blood-vessels lining the nasal cavity, while the asthma which in many cases, sooner or later, makes its appearance in the course of the disease, is a vasomotor paresis of the blood-vessels of the mucous membrane lining the bronchial tubes.

Treatment.—The treatment of hay-fever may be most conveniently discussed under three separate heads, namely: (1) Constitutional; (2) local; (3) treatment of the exacerbation.

1. Leading authorities on the subject of hay-fever are agreed that the disease occurs in the large majority of cases in persons of a neurotic temperament, and that the treatment adopted should be directed toward building up the tone of the nervous

system, with especial reference to the local nervous instability, which manifests itself in the nose, as above mentioned.

(*a*) One of the best agents for securing a good tonic effect upon the nervous system is the daily morning cold plunge, which is to be taken immediately on rising. The immersion need only last for half a minute, followed by vigorous rubbing with a coarse towel. The use of the bath should be commenced several weeks before the usual time for the hay-fever to make its appearance. For those not in robust health, cold sponging of the neck and chest should be resorted to.

(*b*) The mode of life, diet, and exercise should be regulated.

(*c*) Patients suffering from hay-fever are very susceptible to taking cold. They have a tendency to perspire easily, and if they allow themselves to cool off too suddenly, or expose themselves to a draft, they are very apt to bring on a paroxysm of sneezing. Hence suitable clothing and shoes should be worn.

(*d*) The sleeping-room should be well ventilated.

(*e*) Nerve tonics, such as strychnine, arsenic, and phosphorus, are indicated.

2. In nearly all cases of hay-fever there is a pathological condition in the nose, which acts as a predisposing cause to the development of the disease. This being the case, a thorough examination should be made of the nose and nasopharynx of every patient suffering from hay-fever. If any chronic inflammatory condition be found, it should be alleviated; if any obstructive lesion exist it should be removed. All sensitive points should be touched with a caustic, such as a solution of nitrate of silver.

As a rule, hay-fever patients do not come under observation until the onset of the exacerbation, which, however, is not a favorable time for the treatment of the intranasal conditions above mentioned. Whenever possible, patients should be urged to place themselves under treatment in the spring, or at least, several weeks before the time when the symptoms of hay-fever usually make their appearance. By relieving any hyperæmic, or hypertrophic condition, or by removing any nasal obstruction, such as polypi, spurs or deflection of the septum, the severity of the onset of the attack may be more or less diminished. This plan of treatment may need to be renewed at the same period for two or three years, before marked improvement in the severe cases can be expected.

3. The theory that the uric-acid diathesis should be considered as a factor in the production of hay-fever, as taught by such authorities as Haig of London, Bishop of Chicago, and Wilson of Elizabeth, N. J., should be given due weight in our consideration of the treatment of the exacerbation. Dr. Norton L. Wilson (*New York Medical Journal*, December 26, 1896) makes a strong plea for the uric-acid theory in the production of hay-fever. He recommends the adoption of active measures for the treatment of the uric-acid diathesis six weeks or two months before the expected onset of the exacerbation. He suggests the administration of aromatic sulphuric acid, or phosphoric acid, for a time, followed by small doses of salicylate of sodium, three grains three times a day, and cutting off the acid-producing drinks, such as beer, wine, cider, lemonade, etc. The following acid-producing foods, especially meat, should be avoided: all glandular organs, strawberries, coffee and tea, meat extracts, vinegar, sour pickles, preserves, sugar, potatoes, and other starchy food. Ham and bacon may sometimes be allowed. The diet should consist principally of cereals, eggs, fish, fresh fruits, vegetables, milk, and cocoa. Water should be drunk freely. Dr. Bishop recommends that the patient should take one or two teaspoonsful of acid phosphate in a glass of water at bedtime and on rising in the morning.

According to many observers, notably Dr. Beaman Douglas, the most satisfactory agent at our disposal, for internal treatment of hay-fever, is the saccharated extract of the dried suprarenal gland, while the active principle of the suprarenal gland is very efficient in solution in the form of a spray. In the proper doses, the extract of the suprarenal gland, slows the heart, and increases the force of the systole. It retards the pulse and stimulates the constriction of the blood-vessels. The blood-pressure is increased. If a solution of suprarenal extract be applied to a mucous surface, the capillaries become markedly contracted, and the tissues become more or less blanched. Congestion of the nasal mucous membrane is diminished and the watery secretion is rendered less copious and less irritating. The same is true when the active principle of the gland is used.

Dr. Douglas, in his paper, "The Treatment of Hay-fever by the Suprarenal Gland" (*New York Medical Journal*, May 12, 1900), gives 5 gr. every two hours, day and night, until giddiness or palpitation is observed, or until the remedy seems to be controlling the vasomotor paralysis in the nasal mucous membrane. Then the dose may be given at longer intervals, say every three hours, and later every six hours. The amount may even be diminished to two doses of 5 gr. each a day, which are to be continued during the hay-fever season. If disagreeable symptoms of hay-fever recur, the dosage should be recommended as already described. He looks upon it as almost a specific in some cases.

The solution of adrenalin is best used as a spray in the proportion of 1-5000 in normal salt solution. The strength may be increased if found necessary. Prior to its use a spray of some mild alkaline solution may be used, and after its use it is well to apply a bland oily spray. It must be borne in mind that the solution is prone to decompose if exposed to the light. It is therefore necessary to keep it in a dark bottle, and it is also well to protect the bottle attached to the atomizer with a piece of dark paper.

I would advocate beginning the use of the suprarenal extract about two weeks before the time the attack of hay-fever usually occurs, taking 2 gr. three times a day with a view to retarding and mitigating the attack, as far as possible.

The quantity and irritating quality of the secretion of the nasal mucous membrane is diminished by (1) treatment of the uric-acid diathesis; (2) treatment of the intranasal pathological conditions; (3) the use of the suprarenal gland.

Next to the congestion of the nasal mucous membrane, the most important symptom which presents itself is bronchial asthma. According to Bosworth, bronchial asthma occurs, sooner or later, in a large number of cases of hay-fever. In his opinion, the asthma accompanying hay-fever is due to the principal predisposing cause of the disease, namely, a pathological condition in the nose. By directing our treatment to these local causes of irritation the hay-fever and accompanying asthma will be greatly benefited, and in many instances cured.

As regards the medicinal treatment of cases that have more or less asthma during the hay-fever season, the use of the suprarenal gland, both internally and in the form of spray, will be found of service, by improving the tone of the nasal and bronchial mucous membrane. Mention might also be made of the smoking of stramonium leaves. The dried stramonium leaves, as found in the shops, when smoked in a pipe, are kept ignited with considerable

difficulty. A good way to remedy this condition, is to separate the leaves and soak them thoroughly in a saturated solution of nitrate of potassium, then place them on a dish in the oven until thoroughly dry. After being thus treated, the stramonium leaves will burn much more readily, besides obtaining whatever therapeutic advantage there may be in the use of the nitrate of potassium.

When severe paroxysms of asthma occur, compound spirit of ether is of service.

For the relief of the bronchitis, which is often very annoying, the following medicines will be found useful: hydrastis canadensis, terpine hydrate, and cubebs. Dr. Saenger of Magdeburg (editorial, *New York Medical Journal*, May 15, 1897) recommends the use of the fluid extract of hydrastis canadensis in doses of from twenty to thirty drops four times a day, in chronic bronchitis with an irritating cough. I have, myself, found this remedy beneficial. Hare states that terpine hydrate is of value in the bronchitis of hay-fever, by increasing the production of mucus. Cubeb troches are useful and convenient.

One of the drugs which is not much used, but which will often give temporary relief in hay-fever, is camphor. It can be administered either by olfaction or internally. It has a tendency to relieve the congestion and sneezing and to diminish the watery running of the eyes and nose. Its use has an additional advantage, in that it has a tendency to quiet nervous irritability, which is at times a marked symptom in hay-fever patients. Internally, it can be given in the form of spirit of camphor, five drops every fifteen minutes for the first hour, and repeated at longer intervals as required. It should be given well diluted in water.

Aside from medicinal treatment, one of the best methods of obtaining relief from the disagreeable symptoms of hay-fever, is the cold spinal douche, for from fifteen to thirty seconds, at a pressure of from twenty to thirty pounds to the square inch, at a temperature of 60°. This acts as a powerful tonic to the central nervous system. It also relieves the congestion in the nose in a reflex manner, by inducing the contraction of the capillaries in the nasal mucous membrane. The beneficial effects thus obtained may last for two or three hours, or longer. The cold plunge, shower, or cold sponging may be used, but the results obtained are not so favorable nor so lasting. There are few patients who cannot soon become accustomed to the douche, if properly administered and followed by a brisk rub. If an apparatus for giving the douche is not at hand, water from a pail should be dashed over the patient's back, the operator standing at a distance.

Another excellent method of obtaining considerable relief from the nasal congestion and asthma is the use of the ice-bag. The ice-bag is to be partially filled with cracked ice, the pieces being about as large as a white walnut, and then applied to the back of the neck and the upper fourth of the spine. The ice-bag should be kept in this position for ten or fifteen minutes, and then removed. If the application is made as above directed, the relief of the symptoms characteristic of hay-fever is very marked and lasts for several hours. It may be used two or three times a day without untoward symptoms. If applied at night before retiring, the nasal and asthmatic symptoms will be much relieved, so that the patient will be able to get several hours' quiet sleep.

A large number of hay-fever patients find a change of climate beneficial. Most patients are greatly improved by a sojourn in the mountains, and some obtain absolute relief. Others find benefit at the seashore, and by bathing in the ocean. The benefit derived from the surf bathing is not merely due to the stimulant and astringent effect of the salt water, but also to the force with which the water enters the nostrils, acting in a mechanical way, by inducing the contraction of the capillaries and dilated veins. The beneficial effect resulting from a bath in the surf is often marked and lasts for hours. Care must be taken, however, not to remain in the water too long, or after the patient begins to feel chilly, for by so doing the results sought for will not be obtained to their highest degree.

The ocular symptoms in hay-fever are often very annoying. There is apt to be more or less conjunctivitis, which may be rendered more intense by strong sunlight and the irritation of dust. There may be considerable lacrymation and the secretion may be very irritating. For this it is well to use Agnew's eye-water three times a day (boric acid grs. 10, camphor water, 1 oz.). I would also recommend that hay-fever patients wear tinted glasses during the active period of the exacerbation, as at times the reflex action of the bright sunlight on the eyes induces attacks of sneezing, which still further increases the nasal congestion. They also protect the eyes to some extent from irritating dust.

In the treatment of hay-fever we should avoid the use of opium in any form. It should be used only as a last resort, and after all the other means, above advocated, have been given a fair trial.

I would also recommend that the use of cocaine be avoided. We should always bear in mind that the cocaine habit may be formed by its use in a spray. In a large number of cases it will be found that the use of the suprarenal gland, both internally and locally, will give as much relief as was formerly obtained by the use of cocaine.

Patients should be advised to abstain from the use of tobacco during the exacerbation of hay-fever. It has a tendency to produce irritation of the mucous membrane of the respiratory tract and to aggravate any chronic inflammatory condition that may exist.

We should also advise our patients not to indulge in alcoholic stimulants.

In giving directions to our hay-fever patients concerning their diet, mode of life, etc., it will be well to instruct them to avoid walking too fast and getting overheated, especially if the weather be warm and damp or foggy, as under these circumstances asthmatic symptoms are apt to be aggravated. They should also be cautioned against cooling off too quickly, or exposing themselves to draughts.

Patients should be advised to avoid driving in the dust, if discomfort is experienced thereby, such as a paroxysm of sneezing and increased nasal congestion. I know of one case, and have been informed of another, in which the smell of the sweat from the horse when out driving would cause great nasal congestion and discomfort. The first of these patient's could ride in a trolley car or railway car without discomfort, showing that it was not merely the dust that set up the irritation.

In conclusion, I would say that, if the patient can be induced to live in a hygienic way as regards diet, baths, ventilation of sleeping room, exercise, etc., and will carefully carry out the directions of his physician, his attack of hay-fever will be considerably mitigated; and his condition will be still further ameliorated if he can be persuaded to submit to the necessary rhinological treatment, as previously outlined. With patience and perseverance on the part of both physician and patient, it is certain that considerable and, in some cases, lasting benefit may be obtained as the result of treatment.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

IMMUNITY AGAINST INFECTION IN ABDOMINAL SURGERY.

THE prevention of infective disease may be effected in one of two ways, either by offering an obstacle to the entrance into the organism of the offending microbe, or by so strengthening the powers of resistance of the organism that it is able successfully to repel the microbic invasion. The same principles should apply in the domain of operative surgery, since postoperative wound infection is entirely analogous in origin to pneumonia or diphtheria, and in fact we see that they do apply. But in general surgery the first of the two modes of prevention just mentioned, that of exclusion of the germs, is so simple in execution and so certain in result that a resort to the less simple and less certain preventive inoculation would be unjustifiable in most cases. Indeed this method of treatment, which may be called the Jennerian in distinction from the Listerian, has hitherto, with few exceptions, been confined to the prevention of tetanus, unless we may regard the Pasteurian treatment of threatening rabies as a surgical measure.

There is one extensive field of surgical endeavor, however, in which the application of antiseptic principles, while of course not altogether useless, is uncertain in its results because of the impossibility of sealing the wound so as to prevent a subsequent invasion by pathogenic microorganisms. This field is the abdomen. Here then is an opportunity to apply the Jennerian principle in surgery—but how? Manifestly we cannot immunize against the colon bacillus by antistreptococcus serum, nor against Staphylococcus pyogenes by immunization with a strain of Bacillus coli, and it is even doubtful whether we could protect against all the strains of the colon bacillus by a single serum. This being the case, the problem of the prevention of peritonitis after abdominal operations must be attacked in another way.

One possible solution of the problem was the subject of a very interesting discussion by Professor von Mikulicz-Radecki of Breslau in the Cavendish Lecture which he delivered before the West London Medico-Chirurgical Society on June 24 (*The Lancet*, July 2, 1904). After rejecting the suggestion of a specific serum and showing the impossibility of disinfecting the mucous membrane of the stomach and intestine preparatory to operation, he said that the only resort of the surgeon was to increase the power of resistance of the peritoneum against intestinal bacteria by producing an artificial leucocytosis. A number of investigations have shown that, whether the bacteria are destroyed by active phagocytosis alone, or whether the leucocytes produce alexins which kill the bacteria outside the cell body, or whether those two processes work together, general leucocytosis certainly does play a very important part in the struggle against bacteria.

This condition of hyperleucocytosis has been induced artificially by injections (intraperitoneal or subcutaneous) of albumose, decinormal saline solution, bouillon, nucleic acid, and tuberculin. Of these Mikulicz and his clinical assistant, Miyake of Japan, obtained the most satisfactory results with nucleic acid. They found that by subcutaneous injections of nucleic acid in guinea-pigs, it was possible to increase the resistance of the peritoneum to such an extent that even a considerable quantity of intestinal contents could be placed in the peritoneal cavity without causing damage, but without previous treatment an acute, rapidly fatal peritonitis followed almost without exception.

The result of these experiments was so satisfactory that a practical application of the method was employed in man. A two-per cent. solution of nucleic acid was employed and about 50 c.c. was injected beneath the skin of the chest. In the experiments upon guinea-pigs the optimum hyperleucocytosis occurred about seven hours after the injection (the immediate effect during the first hour or so was a hypoleucocytosis), but in man this occurs somewhat later, and Mikulicz has therefore determined upon twelve hours as the proper interval between injection and operation. This ensures that the operation will be performed at the time of the rising tide of leucocytosis.

The proof of a theory lies in its practical working, and the satisfactory demonstration of this can be furnished only by a large number of cases in the hands of many operators. The results of Mikulicz's own cases, however, are such as to encourage others to make a trial of his method. He gave the injections preliminary to forty-five cases of laparotomy, in which the peritoneum was exposed to infection by the contents of the stomach, intestine, or bile ducts. Of the patients operated upon, thirty-eight recovered, and of the seven deaths, not one was due to peritonitis. In most of these cases, in addition to the injections of nucleic acid, the further precaution was taken to flush the peritoneal cavity with warm decinormal saline solution, and it is very possible that that contributed, in some measure, to the successful outcome, as saline irrigations are known to increase the resisting power of the peritoneum.

THE MEDICAL MAN'S VACATION.

THE opinion lately expressed by a financier, noted for personal economy, that vacations are needless and not beneficial to health, has aroused a considerable amount of interest in the matter. Not that the views of the New York millionaire are considered seriously, but because the time for taking holidays has come and the subject is always worthy of discussion. No one really thinks that vacations are unnecessary evils, and that a cessation from work and a change of air and scene are not for the good of toilers. The majority of people will continue to take an annual holiday, and furthermore will derive benefit therefrom to body and mind. All dwellers in great cities require a temporary respite from the noise and turmoil of

the crowded streets, and a period of rest or distraction from the exciting or monotonous routine of daily business. There are indeed some who by reason of their poverty are unable to get away from the town, but are doomed from year's end to year's end to exist among wretched surroundings, compelled by an unhappy fate to labor unceasingly. No one, however, who knows the inhabitants of the tenement districts, will not say that a stay in the country would do them good. In fact, it may be laid down as an axiom that to those who live in modern towns, a vacation is more or less of a necessity. This statement may be made with greater truth of members of the medical profession than those of any other class.

The recommendations as to holidays are widely different. Some advise a long holiday, others a short holiday two or three times a year. One lays stress upon the importance of fresh air and a change of scene, another holds the view that sight-seeing should be strictly eschewed, while yet another will assert that two or three weeks in bed is the most sensible manner of spending a vacation. Lastly, there is the crusty exponent of materialism, who thinks that the vacation idea is entirely a weariness to the flesh and a vexation of spirit, a needless expense for no adequate return, and a grave mistake in most respects. *Quot homines tot sententiæ.* In such jeremiads there is undoubtedly a substratum of truth, insomuch as vacations seldom come up to expectations, and some are total failures. Nevertheless, although perhaps the ideal holiday is seldom or ever found, it does not alter the fact expressed before, that a yearly vacation is needed by every worker, and by no worker more than by the medical man.

The medical profession is, on the whole, the least holiday-making of all the professions. Not a few medical men are literally wedded to their profession; indeed, sometimes the knot is so tightly tied that they never sleep away from home, and when in bed usually have one ear open for the night bell. A great number of practitioners are perforce slaves to work and must content themselves with a week's or, at the longest, two weeks' vacation in the course of the year. The general practitioner, especially in the country, has the greatest difficulty in leaving his practice even for a short time. He and his patients are on terms of such intimate relationship, that, if, when the vacation time has come, those whom he has known for years are grievously sick, he is unwilling to leave them, and if he does go, departs with almost as great reluctance as he would leave a member of his own family under like circumstances.

With regard to the kind of holiday suitable to the medical man, it would be presumption to advise as well as an impossible task. Men's tastes differ as widely as their appearances, while the tastes of their wives and daughters, who must be considered, differ even more widely. In a general way, however, it may be said that the town doctor will be happier and better "far from the madding crowd" in the sweet seclusion of a country retreat. But, although it is well to regard country life from its picturesque and romantic aspect, the matter-of-fact side of the question must not be overlooked. The beauties of rural scenes and of idyllic dwellings are too often the masks which conceal all kinds of evils. The moss and ivy-covered cottage in the woods is frequently but a whited sepulcher. Its drains are defective, its water impure, and its overhanging creepers and surrounding woods and undergrowth are the home of malaria-bearing mosquitos, and keep the health-giving sunlight from its inmates. Such points should not be neglected when choosing a place in which to spend the summer vacation.

The country doctor, upon the theory, or fact, that a change of life and scene is the best way to spend a vacation, should visit the haunts of his busy fellowmen. Perhaps there is no more healthful and pleasant mode of taking a holiday for the country practitioner than attending the meetings of the American Medical Association and of State and County Medical Societies. Such a meeting, for instance, as that which has recently taken place in Atlantic City afforded unbounded opportunities for instruction and amusement to the medical man. At these gatherings he meets and can listen to men eminent in the profession; men from all countries and of world-wide reputation. Such communion is of inestimable advantage in many ways; he receives new ideas, and some of the rust which has gathered upon him in his necessarily somewhat contracted sphere of life is rubbed off. Over and above these advantages, the mixing in the social life of his equals, denied him to a great extent when at home, tends to enlarge his views. The unaccustomed stir and bustle of the town or of the pleasure resort stimulate his faculties, dulled by the monotonous routine of his daily toil, and elevate his entire being, so that he goes back to his work like a giant refreshed. The feminine part of his family can also participate in the social amusements which are a part of present-day medical meetings with equal benefit.

Surgical Treatment of Chronic Nephritis.

In the *Scottish Medical and Surgical Journal*, for May, 1904, Dr. Francis D. Boyd reviews the above subject. The question of surgical interference in chronic nephritis has been greatly to the front within recent years, and especially in this country has gained much ground. Dr. Boyd says that Harrison seems to have been the first to advocate incision of the kidneys in cases in which there was evidence of increased tension of the organs. In America Edebohls has been the most prominent exponent of this mode of surgical procedure—indeed decapsulation of the kidneys is known as Edebohls' operation. Dr. Boyd, referring to the publications by Edebohls on decapsulation of the kidneys, says: "As in the cases in which full details are given, one cannot in several instances accept the diagnosis, it leaves one with an uncomfortable and unconvinced feeling with regard to the accuracy of the observer's conclusions in the tabulated cases."

From a physician's standpoint, the author considers that one of the most important contributions is from the pen of Senator. He denies the occurrence of one-sided nephritis unless there be only one kidney. Nephritis results from causes which are equally applicable to and equally affect both kidneys. After again referring to and criticising Edebohls' views, Dr. Boyd concludes as follows: (1) That while the kidney may undergo a chronic fibrosis as the result of a local cause, the occurrence of a one-sided kidney has not been proved. (2) In chronic diffused nephritis, in

which medical measures have been tried without benefit, decapsulation of the kidneys may be justifiable, and may be undertaken in the hope that relief of tension may facilitate the circulation through the kidneys, may increase urinary secretion, and may produce decided amelioration. The operation does not in itself seem to be associated with such risk as might have been expected. Many of the recorded cases were in a critical condition when operated upon. The benefit in some was so immediate and marked that it can only be accounted for by the relief of tension and improved circulation through the normal channels, not by the formation of new paths for the circulation. (3) The contention that chronic interstitial nephritis may be cured by operation has, so far, not been proved, as the cases on which the claim is founded are so insufficiently recorded as to leave the observer in considerable doubt as to the accuracy of the diagnosis. (4) Surgical measures in affections purely local and for the most part unilateral, such as calculus, pyelitis, pyonephrosis, etc., are eminently successful. In such cases the fibrosis in the kidney is not a true nephritis, and may be benefited by operation. (5) In cases of nephritis, in which cardiovascular changes are advanced, it is unreasonable to expect anything but amelioration of symptoms from decapsulation of the kidneys.

Medical Electricity.

Electricity used in various forms has come to be a valuable adjunct in medicine and surgery, and undoubtedly will in the course of time be a much more important factor in the treatment of diseases and injuries than it is even now. Medical electricity is as yet but in its infancy. Of the many modes of harnessing electricity to the use of the medical man the production of *x*-rays is the most conspicuous, and is fast taking its rightful position as an almost indispensable means of diagnosis in certain cases.

The *Hospital* of May 28, 1904, contains a résumé of the latest literature concerning medical electricity. Brock and Stanley Green have pointed out, in the *Quarterly Medical Journal*, that the *x*-ray tube is of service in the more complete definition of diseased lung in phthisis. They have now had a number of cases to base their deductions upon, and declare that: (1) In no single case in which the physical signs have pointed to disease have the rays failed to detect the mischief; (2) In some cases in which physical signs have been absent the rays have shown deposits in the lungs, and in these cases physical signs have subsequently been detected; (3) The early diagnosis is certainly helped; (4) That the extent of the disease is in many cases shown to be greater than the physician thinks; (5) That the progress and results of treatment can be watched with greater accuracy.

Chisholm Williams, in the *British Medical Journal*, gives favorable testimony as to the beneficial effects of high-frequency currents in the treatment of phthisis. In 1901 he recorded forty-three cases under treatment, and now of these, three have died of pneumonia, of tuberculous kidney, and of lardaceous disease. He advises that the apparatus be of the most powerful available. In tuberculosis of other parts, joints, etc., the best results have been obtained by general electrification combined with a high vacuum electrode used from the resonator, or the ordinary *x*-ray discharge. Cases of old-standing tuberculous lesions he states to be very amenable to treatment. In the treatment of lupus he finds the *x*-ray tube as reliable and to produce as good results as the light treatment. He urges the use of the high vacuum electrodes with a vacuum high enough to produce fluorescence on an *x*-ray screen. Also the patient should receive on the condensation couch as much as 350 milliamperes and upward. In opening the discussion upon the subject of electro-therapeutics in the treatment of malignant diseases, at the annual meeting of the British Society of Electrotherapeutists, Lewis Jones raised numerous questions of the first importance which demand solution ere much advance can be made. Notably is this the case in the matter of what kind of rays are of most advantage—whether the "*x*-rays," "cathode rays," or a combination of the two. He personally recommends the use of a "medium" tube, and prefers to operate with the anti-cathode red hot. He avoids dermatitis by arranging the exposures suitably, and continues the treatment for three, four, or five months.

Alan Jamieson, writing in the *Lancet*, in referring to the employment of hard or soft tubes in *x*-ray work, states that he has found that weather affects the rays materially, *e.g.* on cold, raw days reactions more readily occur. Wild, in the *Medical Chronicle*, has grave doubts as to the prophylactic value of the *x*-rays in preventing recurrence after operation for cancer. A case of splenomedullary leukæmia reported in the Medical Record, August 22, 1903, has been treated by Nicolas Senn with great success, and other similar cases have been since reported.

On the whole, notwithstanding the many instances in which skin diseases, and even malignant diseases of a superficial nature, have been treated successfully by this means, it is as a diagnostic agent that the *x*-rays have yielded the most brilliant results. As remarked before, however, we are only upon the threshold so far as the use of electricity in medicine and surgery is concerned.

News of the Week.

Enforcement of the Law Regarding the Report of Contagious Diseases.—Dr. Thomas Darlington, President of the Board of Health of this city, has addressed a circular to physicians, saying that the health authorities are very anxious to restrict the prevalence of infectious diseases, and increase the accuracy and completeness of the vital statistics of the city, and that they intend, therefore, to enforce strictly the provisions of the Sanitary Code in regard to the reporting of contagious diseases and births. According to Section 133 of the Sanitary Code, it is the duty of every physician to report to the Department of Health, in writing, the full name, age, and address of every person suffering from any one of the infectious diseases included in the following list, with the name of the disease, within twenty-four hours of the time when the case is first seen: Contagious (very readily communicable): Measles, rubella (rotheln), scarlet fever, smallpox, varicella (chicken-pox), typhus fever, relapsing fever. Communicable: Diphtheria (croup), typhoid fever, Asiatic cholera, tuberculosis (of any organ), plague, tetanus, anthrax, glanders, epidemic cerebrospinal meningitis, leprosy, infectious diseases of the eye (trachoma, suppurative conjunctivitis), puerperal septicæmia, erysipelas, whooping-cough. Indirectly communicable (through intermediary host): Yellow fever, malarial fever.

The American Medical Association in 1905.—The date set for the next session of the American

Medical Association is July 11-14, 1905. This date has been decided on after considerable correspondence. The holiday season for the majority of medical men is from about the first week in July to September, and the schools have by that time all closed. Most of those who live in the east will want to utilize the trip to the association meeting as their summer vacation, and if the date were that usually adopted for the association meeting, these would not be able to attend. In July Portland has a delightful climate, and consequently there need be no fear of hot weather.—*Journal of the American Medical Association.*

The White League of Pennsylvania has been chartered for the purpose of providing open-air treatment for patients suffering from tuberculosis and unable to provide for themselves. A farm has been secured in Luzerne County, near Glen Summit, where a permanent camp will shortly be built. A temporary camp will soon be opened at Trout Run, near Bethlehem, with provision for ten patients. In addition to the camp a hospital is to be built on high ground about ten miles from Philadelphia.

Cholera is epidemic in Teheran, Persia, the deaths numbering several hundred daily. One of the recent victims was a New York merchant who has resided there several years. Dr. Allen, the American minister at Seoul, reports that cholera has appeared at An Tung, and that both of the belligerent armies in Manchuria are in great danger from the spread of the disease. The health authorities in Russia fear that the disease may invade their country from one or both of these sources, and precautions are being taken to prevent such a calamity.

Report on Cancer.—The committee of the Cancer Research Fund made a report at the annual meeting held in London last week. Some of the assertions made are rather too dogmatic and positive, as transmitted by cable, to preserve an altogether scientific tone, but doubtless the condensation of the reporter is accountable in part for that. The committee said that cancer was not caused by a parasite and was not transmissible from one person to another. It was denied that cancer was on the increase, and the effect of civilization on the incidence of the disease was declared to be nil, since animals were sufferers equally with mankind. It was declared that radium had no therapeutic influence on malignant growths, but hope was held out that curative results might be obtained from a serum which the committee had elaborated.

Newport, Ky., Branch Hospital.—In a decision handed down July 8 by Judge Berry in the Circuit Court, the city of Newport is restrained and enjoined from locating or maintaining within a mile of the boundary lines of the Coldspring District any branch hospital or institution where cases of contagious disease may be treated. It was thought that the location of the branch hospital on the Alexandria pike, about five miles out of Newport, had proved a solution to a very vexing problem. Four thousand dollars was paid for the ground and house, and about $1,000 was expended in fitting the place up, after numerous other attempts to locate a branch hospital had proved futile, because of the hostility of persons residing in the vicinity. The city will probably take an appeal.

The Association of Surgeons of the Baltimore and Ohio Railway met in the parlors of the Hamilton Hotel in St. Louis, June 29, 30, and July 1. At the meeting Dr. H. B. Stout of Parkersburg, W. Va., introduced a measure to secure the cooperation of the surgeons in a general plan to give lectures and instructions to conductors, engineers, brakemen, and firemen at all division points regarding the treatment of injured persons. Officers elected were as follows: *President*, H. Slicer Hedges of Brunswick, Md.; *Vice-President*, N. R. Eastman of Belleville, Ohio; *Secretary-Treasurer*, G. A. Davis of Summit Point, W. Va.

Joint Meeting of the International Association of Railway Surgeons and the American Academy of Railway Surgeons.—A joint meeting of these two societies was held in Chicago, Ill., June 1, 2, and 3. The convention met in the Assembly Hall of Northwestern University. During the first day the sessions were presided over by Dr. James H. Ford of Indianapolis, President of the International Association of Railway Surgeons, and the sessions of the second and third days by Dr. S. C. Plummer, President of the American Academy of Railway Surgeons. An address of welcome was delivered by Dr. Wm. A. Evans of Chicago, which was responded to by Dr. George Ross of Richmond, Va. President Ford discussed the "Use and Abuse of the Railway Surgeon" in his presidential address; and President Plummer selected, as the title of his address, "Following and Assisting Nature." Many papers were read and discussed. A resolution was introduced and adopted unanimously to the effect that the International Association of Railway Surgeons dissolve its present organization for the purpose of organizing the American Association of Railway Surgeons, provided that a union be made with the American Academy of Railway Surgeons; and also that the executive board of the International Association of Railway Surgeons be authorized to join with the executive board of the American Academy of Railway Surgeons and organize the American Association of Railway Surgeons. The following are the officers of the new organization, the American Academy of Railway Surgeons: *President*, Dr. John E. Owens, Chicago, Ill.; *Vice-Presidents*, Dr. R. W. Corwin, Pueblo, Col.; Dr. G. D. Ladd, Milwaukee, Wis., and Dr. H. C. Fairbrother, East St. Louis, Ill.; *Treasurer*, Dr. T. B. Lacey, Council Bluffs, Iowa; *Secretary*, Dr. H. B. Jennings, Council Bluffs, Iowa; *Editor*, Dr. Louis J. Mitchell, Chicago; *Executive Board*: Drs. D. S. Fairchild, Des Moines, Iowa, and A. I. Bouffleur, Chicago, three-year term; Drs. S. C. Plummer, Chicago, and A. L. Wright, Carroll, Iowa, two-year term; and Drs. W. S. Hoy, Wellston, Ohio, and J. R. Hollowbush, Rock Island, Ill., one-year term. There was considerable discussion relative to the time for holding the next annual meeting, but this matter was left entirely to the executive board. It is probable that the meeting will be held next year some time in the autumn.

New Jersey State Medical Licentiates.—At the meeting of the State Board of Medical Examiners of New Jersey, held at Long Branch, July 5, forty-three candidates for a State medical license, who passed the examination at Trenton on June 21-22, were licensed. The candidates represented twenty medical colleges located in Boston, New Haven, New York City, Brooklyn, Syracuse, Philadelphia, Baltimore, Washington, Chicago, Toronto, and Naples, Italy. The following attained the Honor Roll, or a general average of 90 and upward: Dr. Louise Martha Sturtevant, A.B. of Wellesley, and M.D. of Boston University School of Medicine, attained 91.6; and Dr. Henry Augustus Craig, M.D., of Columbia University, attained 90.7. The following Officers were elected for the ensuing year:

President, Dr. William H. Shipps, Bordentown; *Secretary*, Dr. E. L. B. Godfrey, Camden; *Treasurer*, Dr. Charles A. Graves.

Ohio State Board Examinations.—The Ohio State Board of Medical Registration and Examination announced on July 5 the result of the recent examination. Out of 222 candidates 210 were found to be entitled to a license. Of these, 39 reside in Cincinnati and 30 in Cleveland.

Agitation for a New Milk Law in Chicago.—Dairy inspection as a means to insure a pure milk supply for Chicago is not considered strong enough, as the Chicago Milk Dealers' Association, in a letter to Health Commissioner Reynolds, attacked the present system and made a plea for the permit system. The Health Department Bulletin states that inspectors will be sent into the country for the purpose of conferring with and advising the farmers. During 1900, with one city dairy inspector, only eleven farms were inspected. Without a change in conditions and methods, it is not expected that four inspectors can report upon more than forty-four of the 4,000 dairy farms. The Chicago Milk Dealers' Association believes in trying a system which has been of untold value in other cities. It believes that the city should require that any one who sends milk into Chicago should secure the privilege and make annual affidavits that the sanitary conditions prescribed by the city have been complied with. This plan is incorporated in a proposed amendment to the ordinance which provides that in applying for permits the dairyman furnish information regarding the location of the farm, the number, health, and feed of the cows, the drainage, light, and ventilation of the stable, methods of handling the fresh product, and the health of the employes. The association also advises that the ordinance require shippers to seal milk cans coming into the city, to prevent them from being tampered with while on the way. Instead of fining the receivers of the unsealed cans, as is the present rule, this new arrangement would place the punishment where it belongs, and make the shipper suffer for the negligence.

International Electrical Congress of St. Louis.—An International Electrical Congress will be held in St. Louis, during the week September 12 to 17. The congress will be divided into two parts, namely, (1) A chamber of government delegates appointed by the various governments of the world, invitations to which were issued at the beginning of the year from the United States Government. The transactions of the Chamber of Delegates will relate to matters affecting international questions of electrical units, standards, and the like. (2) The congress at large, divided into eight sections, one of which is for electrotherapeutics. The chairman of this section is Dr. W. J. Morton, New York City, and the secretary is Mr. W. J. Jenks of New York City. Three hundred and forty-three official invitations were issued some months ago to well-known workers in electricity, inviting papers for the congress. One hundred and sixty-eight of these invitations were issued to persons residing in countries outside of North America. As a result of these invitations, 105 American and 59 foreign specially prepared papers are promised to the congress. Of these, 5 foreign and 15 American papers are in the section on electrotherapeutics.

The Late Dr. William E. B. Davis.—The Southern Surgical and Gynecological Association proposes to honor the memory of its founder, Dr. W. E. B. Davis, late of Birmingham, Ala., by erecting a bronze statue of him. The statue will be unveiled at the meeting of the association in Birmingham, December 13 to 15, 1904.

American Academy of Ophthalmology and Otolaryngology.—The ninth annual meeting of this society will be held at Denver, August 24-26, 1904, under the presidency of Dr. Edward Jackson of Denver. The secretary is Dr. Derrick T. Vail of Cincinnati.

The Germantown Hospital, Philadelphia, has, by the gift of Anna T. Jeanes, come into possession of a handsome residence on Locust Avenue, near Chew Street. The income from the rental or sale will be devoted to the purposes of the hospital. Ground has been broken for the erection of a laboratory adjoining the hospital at a cost of $2,500. This is the gift of Mr. John D. McIlhinny, in memory of an infant daughter. The building will be one-story high and will be used for pathological and bacteriological investigation. A new building for pay patients, erected at a cost of $100,000, raised by popular subscription, will be ready for occupancy in the latter part of July. It is a three-story fire-proof structure, containing twenty-five private rooms and a special operating room.

Home for Nurses at Jewish Hospital.—The contract for the construction of the Nurses Home at the Jewish Hospital, Cincinnati, has been let. The building will be three stories in height and cover a plot of ground measuring 35 feet front, with a depth of 67 feet. It will be built of brick, with trimmed stone dressing.

A School in Philanthropy.—The success of the summer school in philanthropic work, which has been in operation in this city for seven years, has been so great that a permanent school of that character is to be established. The first session will begin early in October under the direction of Mr. Edward T. Devine.

Dr. Adam Szwajkart has been appointed by Governor Yates a member of the West Park Board, to represent the Sixteenth Ward. He is a graduate of the University of Cracow, and of the Medical Department of the University of Illinois.

Erection of New Hospital.—Within a few months the Columbus Hospital at Lake View Avenue and Deming Place, Chicago, which is under the management of the Missionary Sisters of the Sacred Heart, will be erected, sufficient funds having been already received to insure the success of the venture. The hospital will be five stories in height, and will be equipped with 150 rooms and 20 nurses.

Hamilton County, Ohio, Coroner's Report.—There were 103 suicides in Hamilton County during the year ending June 30, according to the annual report of Coroner Weaver. Of these all were white, with the exception of two colored women. It is a matter of record that few negroes commit suicide. Coroner Weaver also investigated 32 homicides and 358 accidental deaths. His attention was called to 334 deaths due to natural and unknown causes. Seven persons died from alcoholism and the inquests aggregated 834.

A New Journal.—The Missouri State Medical Association has decided to publish its transactions in the form of a monthly medical journal and the initial number of the *Journal of the Missouri State Medical Association* appeared on July 1. Dr. C. M. Nicholson is editor, assisted by Drs. C. Lester Hall, F. J. Lutz, Woodson Moss, M. P. Overholser, Robert T. Sloan, and L. A. Todd.

Professor Hoffa of the University of Berlin delivered a lecture in Germany's section of the Educational Exhibit at the World's Fair in St. Louis, on June 25. The subject of the lecture was Coxa Vera, and it was elaborated by some beautiful specimens and excellent radiographs. About fifty leading St. Louis physicians attended the lecture and a banquet which was given later in honor of Professor Hoffa.

Dr. Elias Potter Lyon of the department of physiology and dean of the medical department of the University of Chicago has resigned his position to become head of the department of physiology in the medical department of St. Louis University.

Anti-spitting Ordinance.—Moline, Ill., has adopted an anti-spitting ordinance, with penalties varying from one to five dollars for its violation. Signs are to be posted to warn the strangers, the careless, and the unwary against inadverently spitting on sidewalks.

Coroner's Fees Inadequate.—The County Officials of Hamilton County, Ohio, have recently gone back from the salary system to the old fee system. This is welcome to most of them, but in the Coroner's office the salaries amounted to $8,100, while the annual fees amount only to about $4,100. The Coroner, Dr. Weaver, is searching the statutes for relief.

The Chicago Hospital.—The Chicago Hospital Building Company, a corporation formed to build the Chicago Hospital at 452 Forty-ninth street, has given a deed of the property to the Chicago Hospital for a consideration of $135,000. The property is located 110 feet east of Cottage Grove avenue, and has a frontage of 75 feet and a depth of 132 feet. The improvement consists of a five-story brick building. The transfer was made subject to an incumbrance of $30,000, and the grantee has given a trust deed to the Merchants' Loan and Trust Co., to secure an additional loan to John T. Binkley of $40,000 for five years at 5 per cent.

A New Sanatorium at Denver.—The Agnes Memorial Sanatorium, for the treatment of pulmonary tuberculosis, was opened on July 2, Denver, with fitting exercises. The sanatorium was built and furnished by Lawrence C. Phipps in memory of his mother, Mrs. Agnes Phipps.

The California Vaccination Law.—The Supreme Court of California has reaffirmed the constitutionality of the "act to encourage and provide for a general vaccination in the State." The decision was rendered in a case referred from the county of San Diego, where the antivaccinationists have been creating no little trouble for the school board.

St. John's Hospital Made Free.—The board of managers of St. John's Hospital, in Brooklyn, which is under the control of the Church Charity Foundation of the Episcopal Diocese of Long Island, have decided that after July 1, no more pay patients will be admitted to the institution. Hereafter the work is to be of a purely benevolent nature. The number of patients for the present will be limited to the number of endowed beds.

"The Medical Digest" is the name of a new journal published in Portland, Me. The editors are Dr. Ralph Opdyke of New York and Dr. Eugene D. Chelbis of Portland. The paper is to appear monthly, the first number being dated April, 1904. The early issues give promise of a useful and successful periodical.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

BIRTHDAY HONORS—FASHIONABLE BAZAAR FOR VICTORIA CHILDREN'S HOSPITAL—HARVEIAN ORATION—RETURN CASES OF DIPHTHERIA AND SCARLET FEVER—POST-OPERATIVE VENTRAL HERNIA—ST. GEORGE'S HOSPITAL—SLADEN MEMORIAL—OBITUARY.

London, June 24, 1904.

To-day the King's birthday is officially celebrated and a list of honors conferred on the occasion was issued last night. Among them Mr. C. Holman, the zealous treasurer of Epsom College, and Dr. Thos. Stevenson, Home Office Analyst, receive knighthoods. In the order of the Bath, Deputy Surgeon-General Thornton, I.M.S., C.B., and Surgeon-General Townsend, C.B., become K.C.B. Surgeon Ligertwood, formerly surgeon Royal Hospital, Chelsea, and Surgeon-General Fawcett, Army Medical Staff, receive the C.B.

The Queen was present for about an hour at the opening of a grand bazaar at the Albert Hall on Tuesday, in aid of the Victoria Hospital for Children, and subsequently sent a letter to the president, congratulating him on the beautiful appearance of the hall. The sight has been described as "Fairy land in London," the stalls and decorations illustrated nursery rhymes and, of course, the assembly of ladies was most brilliant. On Wednesday Princess Louise, Duchess of Argyle, opened the second day's sale. Yesterday the sale concluded and a grand ball was held in the evening. Over £15,000 was realized, and after all expenses I hear the hospital will receive about £11,000.

The Harveian Oration at the Royal College of Physicians was delivered on Tuesday, by Dr. Richard Caton of Liverpool. He divided his discourse into two parts. The first dealing with Egyptian medicine, in which he gave an account of some of the results which archæological research has arrived at, in reference to the dawn of medical practice. About 3500 years B. C., the medicine-god, I-em-Hotep, whose name means "he who cometh in peace," was probably a priest of Ra, physician and sun god. From inscriptions and papyri his temples, where healing was carried on, were, in fact, hospitals. The later Greek colonists called them *asklepieia*. His priests also practised embalming and so acquired definite anatomical ideas. In the Ebers papyrus is a passage which the orator quoted as "wise advice," the importance of which we have, he suggested, scarcely as yet recognized. It was to the effect that in heart disease, if possible, the heart should be made to rest somewhat, and with this I pass by many interesting remarks to the second subject of Dr. Caton's able oration. This was devoted to the prevention of valvular disease. Why do rheumatic joints recover and the endocardium not? asked Dr. Caton, and replied, because the joint can rest but the heart cannot intermit its labors. But it may be made to rest partially, and this has been his practice for twenty years. He enjoins absolute quiet, the patient to lie with head at low level, made as comfortable as possible, encouraged to sleep, no excitement being permitted, and pain or fever being subdued—in short, he seeks to attain the nearest possible approach to physiological rest, as enjoined by our Egyptian predecessors thousands of years ago. We may add iodides to promote absorption of exudations but chiefly to lower tension, as in aneurysm. Of this plan Dr. Caton spoke most confidently, after carefully following it for over twenty years.

Dr. A. Newsholme read a paper at the Medical-Chirurgical Society on protracted and recrudescent infection in diphtheria and scarlet fever. Protracted infection in diphtheria was recognized by Greenhow and Gresswell, but not until recently has it been observed in scarlet fever. It doubtless occurred before the period of isolation hospitals, and Dr. Newsholme would explain by it the persistent belief in the infectiousness of late desquamation. He examined the explanations offered of return cases, which he said were relatively rare, and did not invalidate the value of isolation hospitals. These cases were generally connected with otorrhœa or rhinorrhœa, though in some cases a dormant infection might be roused into activity by catarrh. Germs multiplying in the patient himself and collecting on the rhinorrhœal lesion with which return cases are generally admitted would be more numerous than the lesser number that could obtain ingress from other patients. That increased activity was caused by hospital aggregation was a mere theory borrowed from that of smallpox. In each case it is a theory in support of a theory. Relapses of scarlet fever were compared with those of enteric, and these are not caused by fresh external infection.

At the Gynecological Society, on the 19th inst., Mr. Ryall exhibited a giant myoma which had been removed by Mr. Jessett, although a previous attempt at another

hospital had been abandoned. Intravenous transfusion was called for. The patient did well. The tumor weighed twenty-six pounds. Other cases were mentioned by those present—one in which the tumor was over twenty-eight pounds, another twenty-two and one-half pounds.

At the same meeting, Mr. Stanmore Bishop started a discussion on the prevention of post-operative ventral hernia, of which he had had four cases in more than 350 abdominal sections. He urged the necessity of securing firm union of the peritoneum, fascia and skin, as well as the combined tendons of the transversalis and oblique muscles. He discussed also the materials for sutures, their sterilization and preservation, and showed apparatus for securing these objects.

Dr. Macnaughton-Jones said he usually closed the abdominal wall in the manner shown in Mr. Bishop's diagram, which was practically the plan of Noble of Philadelphia, who had lately introduced another method of suture (diagram exhibited). The speaker closed the peritoneum by a fine continuous cumol suture, dissected the fascia from the rectus, and united it by continuous suture passing through the fascia and looping up the muscle at either side, before penetrating the fascia at the opposite side, thus closing the wound by complete adaptation or slight overlapping of the aponeurosis through its entire extent. Any apparently weak points can then be secured by interrupted sutures.

Mr. Charles Ryall said the chief thing was to be sure the aponeurosis was united throughout the length of the wound. The union of muscle would not prevent hernia; that of peritoneum did not add much strength though important in preventing adhesions. Prolonged rest after operation was an important preventive.

Dr. J. J. Macau regretted the absence of those who still used the through-and-through suture. Since the almost general adoption of suture in layers, subsequent hernia had been less frequent and less severe.

Professor Taylor (president) had found in the post-mortem room that union which seemed perfect externally might be incomplete on the peritoneal surface. For some eight or nine years he had united the peritoneum with a continuous suture of the very finest silk sterilized by boiling in a benzine solution. He then passed sutures at about one-half inch intervals through skin, fascia, and muscle without including the peritoneum, but before tying these, he united the fascia for the whole length of the wound, with a close continuous suture of the same fine silk as used for the peritoneum, over which, if desirable, a horsehair suture could be tied and passed through the skin. The interrupted sutures supported the fine ones and after ten days were withdrawn. The silk ones were left. He had seen indications of them two months afterward. In another case, reopened after a year, they had completely disappeared. In only three cases had silk given trouble and they occurred before he used benzine.

Mr. Bishop, in reply, said all agreed that buried sutures should be absorbable. Neither wire nor catgut were; the latter was apt to give way, and if used of the thickness often tried (No. 8) was almost impossible to sterilize; if one could rely on catgut being germ-free the difficulty would be met. By his method it was easy to assure one's self by both sight and touch that the aponeurosis was properly united throughout its entire length.

A special court of the governors of St. George's Hospital was held on Tuesday, to receive the report of the committee appointed in March, 1903, to consider the desirability of removing the hospital to a more extensive site. There was a large attendance, and Lord Windsor presided. The majority of the committee were against removal but there was a minority report. In accordance with the majority, a resolution was moved "that it is not desirable at the present time and under existing circumstances to remove St. George's Hospital from its present site." It was urged that this site was one of the best in the world. On the other hand, it was argued that the hospital is spending at the rate of £10,000 beyond its regular income and a sale of the site would cover that. The resolution was carried. A resolution that the present is not a favorable time to appeal for funds for rebuilding was defeated. Resolutions were carried for utilizing the new site lately acquired for the immediate requirements of the hospital, and authorizing negotiations for the acquirement of additional leaseholds. Just before the close of the meeting a letter was read from Dr. Rob Barnes offering £1,000 toward the expenses of the medical school.

Mrs. Percy Sladen, to perpetuate the memory of her late husband, Mr. Walter Percy Sladen, at one time vice-president of the Linnean Society, has undertaken to devote the sum of £20,000 to the promotion of research or investvestigations in natural science, more especially in zoology, geology, and anthropology. Mrs. Sladen has appointed the first trustees of the Percy Sladen Memorial Fund—four in number.

Edward Trimmer is a name appended to thousands of diplomas of the Royal College of Surgeons during the forty-two years he served that corporation as secretary. He retired in 1901. After some months' suffering from malignant disease he has just passed away in his seventy-eighth year.

Sir David P. Ross, late Surgeon-General of British Guiana was M.D., Edinburgh, 1863, and M.R.C.S., England, 1864. The same year he entered the army service. Was for twelve or thirteen years in various medical posts in Jamaica; and his subsequent career in the colonial service has been distinguished. In all his varied positions, from a student onward, he was esteemed by hosts of friends and colleagues.

The death of Mr. A. O. Mackellar, F.R.C.S., Chief Surgeon of the Metropolitan police force and formerly surgeon to St. Thomas' Hospital, occurred on the 15th inst., at the age of fifty-eight. He was M.D. and M.Ch. of the Royal University, Ireland, 1869. He went out to serve as surgeon on the ambulances sent to help in the Franco-Prussian, Turko-Servian, and Russo-Turkish wars, was made Knight of the Military Order of Merit of Bavaria, of the Gold Cross of Takovo, and of the order of the Medjivich.

OUR PARIS LETTER.

(From Our Special Correspondent.)

SERPENT VENOM—MILLIAMPÈREMETER FOR X-RAYS—BREAST-FEEDING FOR THE CHILDREN OF FACTORY WORKERS—X-RAYS IN CANCER—SOCIAL ASPECTS OF MEDICAL CHARITY—POISONING BY CAMPHOR—NAPHTHOL—DEATH OF PROFESSOR MAREY.

PARIS, June 10, 1904.

At the Académie des Sciences, Calmette recently presented the result of his investigations concerning serpent venoms and their antagonistic serums. He differentiated two distinct substances in these venoms, one acting on the blood, the other on the nervous centers. The antitoxic activity of an antivenomous serum is easily determined by experiments in vitro, in which varying amounts of antitoxic serum are made to act on a constant quantity of the defibrinated blood of the horse or of the rat, containing a constant amount of venom. D'Arsonval presented a milliampéremeter intended to measure the intensity of a current circulating in an *x*-ray tube. This method will make it possible to record, rapidly and practically, the strength of the Rontgen rays emitted by a tube.

At the Académie de Médecine, in the session on May 24, Professor Budin made an interesting report on the necessity of breast-feeding for the children of workers in mills and factories. The Academy afterward indorsed this report and forwarded it to the Minister of the Interior. The figures show that among children who die under one year of age nearly half are overcome by diseases of the digestive tract. The great cause of these diseases is artificial feeding; therefore nursing ought to be made possible. The labor organizations should be prevailed upon to permit women to nurse their children. Professor Budin calls to mind the fact that the Italian Parliament enacted a law in 1902 that in all factories occupied by as many as fifty workers there should be a room for nursing.

The Academy should, the speaker urged, express the opinion that in all industries and establishments mothers ought to be authorized to absent themselves regularly to nurse their children, and that créches and special rooms should be established near the places for work, where the children could be cared for and nursed.

At the meeting of the Société des Internes et Anciens Internes des Hôpitaux de Paris, held May 26, Dr. Leredde showed two patients with epithelioma of the face, who had been subjected to the action of the Röntgen rays during only five or six exposures of from thirty to forty minutes each. The photographs of these patients, taken before the treatment, showed considerable epitheliomatous masses, situated in one case on the left cheek, in the other on the forehead. The presentation of the patients themselves gave the opportunity of noting the disappearance of the neoplastic masses. Following this presentation, an interesting discussion arose in regard to the action of *x*-rays on epitheliomata. Cancerous tumors in active proliferation, malignant epitheliomata, seem clearly to be influenced, retarded in growth, and even destroyed by the Röntgen rays. The hard, horny tumors, on the other hand, show no well-marked effect. As to the influence of the Rontgen rays on internal cancerous tumors, this appears to be rather adverse than otherwise. Indeed, Dr. Jacquet cited a case in which the *x*-rays evidently hastened the death of a patient suffering with inoperable carcinoma of the stomach. Dr. Pechon also cited a case of non-ulcerating sarcoma of the thigh, treated by exposure to *x*-rays, which was followed by general sarcomatosis and the death of the patient.

Mesureur, director-general of the "Assistance Publique," delivered a remarkable address, at the same meeting, on

the social rôle of the "Assistance Publique." He showed how, since the adoption of the altruistic ideas advanced by the French Revolution, the dignity of the indigent patient has been actually safeguarded, and how he has not been considered, as formerly, a dangerous element, and one prejudicial to society. Since the alleviation of misery devolves upon the "Assistance Publique" it ought preeminently to consider its prevention by means of social laws. Laws for the protection of the woman and the child give, from this point of view, an immediate and certain return, for in safeguarding their health and their capability for work, both the woman who is to be the mother and the child who is to be the citizen and the soldier of the future are protected.

A great project, the most important, perhaps, which would considerably lessen the debt of the "Assistance Publique," is that which relates to the relief of the aged and incapacitated workers, and to the provision of homes for the superannuated. Thus Society, diminishing little by little the causes of misery, establishing the right of the individual to the consideration of humanity, will finally cancel its debt to humanity. And yet, no laws can wholly do away with misery and illness, for there will always remain some who are starving and some who are ill. The "Assistance Publique" is indeed at hand, as an automatic instrument, to distribute succor, to relieve the hunger of a day, but never, by itself, will it raise up again a being who has fallen. To its official efforts must be added the disinterested help of private individuals who will give that useful counsel, that moral support, which will reawaken dormant energy, will arouse the power for work, and will give assurance for the future.

It is in the hospital that the divers forces of this charity can unite. The patients, in effect, in coming to the hospital, largely pay their social debt by constituting the vast field where science reaps its harvests, where all the youths of our scientific schools find the essential material for their studies. Passive and apathetic, the patients contribute their part to the progress which has made the renown of the French medical schoo so wide spread. The "Assistance Publique" considers that its honor lies not only in the fact that its hospitals afford an asylum for those who suffer, but also in the fact that they constitute a great practical school in which the country may take pride. It demands that the physician love these who so generously offer their sufferings as a means of instruction, love them in order to cure them, and also that he recognize in the patient a human being whom a word can console. It demands that these guardians of science, these intellectual giants, who have dedicated their great powers to the cause of healing, shall endeavor, by arousing a greater sympathy among men, to create a better society, with less of suffering and more of justice.

At the Society of Surgery, the question of intermittent hydronephrosis, of which we spoke in our last letter to the MEDICAL RECORD, was again discussed. Dr. Guinard then reported a case of poisoning by camphor-naphthol, in which a man succumbed a few minutes after its injection into the cavity of an abscess from which the pus had just been evacuated. Kirmisson also cited cases in which camphor-naphthol injections had produced untoward accidents. The symptoms always take the same form, that is, either syncope or epileptiform attacks. Guinard stated as conclusion of his communication and of the discussion which followed, that it seemed to him the administration of camphor-naphthol by this method should be discontinued.

Among the serious losses which the scientific world has recently experienced we would mention the death of Professor Marey, member of the Academy of Medicine and of the Academy of Sciences, whose works on experimental physiology are well known. The sphygmograph and the cardiograph of Marey are instruments too widely distributed, too generally adopted throughout the world, and of a usage too common, for it to be necessary to lay stress on the great discoveries of this savant. During more than forty years, indeed, Marey devoted himself to the difficult problems of the heart and the blood-vessels. His great work was the development of the graphic method, that is to say, the direct inscription through the medium of pens of the biological phenomena observed. By a series of photographs Marey was able to study and to recognize all the phases of the circulation of the blood in men and in animals. Moreover, he made an interesting and valuable study of the flight of birds and of the various movements of their wings.

Health Board Changes.—Commissioner Darlington has again shifted the assistant sanitary inspectors. Dr. Moore, who was sent from Queens to Richmond, two weeks ago, goes back to Queens; Dr. Sprague, who was sent from Richmond to the Bronx, comes to Manhattan; Dr. Murray, who went from Brooklyn to Queens, goes to Richmond. Dr. Pursall, who went from Manhattan to Brooklyn, will remain there one week longer.

OUR BERLIN LETTER.

(From Our Special Correspondent.)

QUINQUAUD'S DISEASE—BERLIN LIFE-SAVING SOCIETY—ECLAMPSIA AND THE NERVOUS SYSTEM—INFANT MORTALITY—FIRST REPORT OF MEDICAL SCHOOL INSPECTORS.

BERLIN, June 4, 1904.

At the meeting of the Society for General Medicine, held May 16, Fürbringe delivered an address concerning the value of Quinquaud's sign. The inquiries of many physicians had caused the speaker to give closer attention than before to the nature of this sign. Speaking of its history, he told how a teacher by the name of Quinquaud, as Maridon made known in 1900, made the following experiment with his scholars in 1893: He had them place the finger tips of a patient against the palm of his hand, and held them there a few minutes. Among the students several were evidently scornful. In a little while crepitation was apparent in the phalangeal joints of the fingers that had been placed in position. This phenomenon can be observed only in the case of drinkers, and then not with moderate drinkers. The degree, therefore, to which alcohol has been misused can be judged by the strength of the crepitation. Fürbringe examined in this way five hundred patients, drawing them from both the hospital and his own private practice. He divided those whom he examined into four groups: almost total abstainers, moderate drinkers, drinkers, and drunkards. He divided the sounds observed into three groups: perceptible, moderate, and strong. In the case of the drinkers, he found it sufficient if they placed two fingers only in position, the two chosen being the ring and the middle finger. He prepared the following table:

	Moderate Drinkers	Drunkards
Absent,	89.5 per cent.	10.5 per cent.
Moderate,	72 per cent.	28 per cent.
Strong,	41.5 per cent.	58.5 per cent.

In brief, it may be said that in the case of the moderate use of alcohol, this phenomenon occurred only to a slight degree, and that where it was more marked, the case was that of a drunkard. In comparing tremor with this sign, Fürbringe made the following table:

	Moderate Drinkers	Drunkards
Absent,	93 per cent.	7 per cent.
Moderate	73 per cent.	27 per cent.
Strong,	22 per cent.	78 per cent.

It is evident from these tables that one can recognize a drunkard with greater certainty by tremor than by Quinquaud's sign. It is to be noticed that neurasthenia and hysteria influence both these phenomena. In no case was there any change in the joints. The phenomenon ceases when the subject is tired, but reappears after a short time. Fürbringe drew the conclusion that Quinquaud's sign should not be taken alone in making the diagnosis of alcoholism, but it is of value in connection with other symptoms.

The recently published report for 1903 of the Berlin Life-saving Society gives the opportunity for a few general remarks concerning the present situation and the outlook. In the case of street accident or sudden illness in a house, the sufferer heretofore would receive help first from the stations established by the Red Cross Society. There are twenty of these stations in Berlin, with their directors and assistant physicians, who, it is said, know how to make a very good practice for themselves from the patients who come to the station, and have made inroads upon the practice of the physicians of the district. In spite of this, the number of stations established was not increased according to the demand. Seven years ago the Berlin Life-saving Society was founded by Morris von Bergmann, and this society at the present day has fifteen head stations, chiefly in the cities and in connection with the royal hospital, and also ten relief stations. In the latter, each physician of the district is on duty from two to four hours every week. Care is taken that one in laying claim to the help of a station does it but once in the course of an illness. The Life-saving Society is doing a very great work through the introduction of a central station for the care and attendance of the sick of Berlin, concerning the great social and humanitarian significance of which movement we shall speak later. According to the yearly report, 6,074 cases were treated in the chief stations, and 10,946 in the relief stations. The increase since last year has been remarkable. A year ago union with the accident stations was refused by the Life-saving Society, but on April 19, 1903, a common agreement for first aid was established.

An interesting discussion took place at the meeting of the Obstetrical and Gynecological Society. It had to do with the still unsolved problem of the cause of eclampsia. Bruno Wolf had repeated the well-known experiments of Blumenreich on animals, in which he removed

both kidneys from a large number of rabbits, some being pregnant, and some not. He made the following important deductions: (1) In the case of a pregnant animal, both of whose kidneys have been removed, the fœtus dies before the appearance of any uræmic symptoms in the mother. (2) Typical uræmic attacks, with convulsions, occur very seldom after the operation—twice out of seventy-four cases. Blumenreich believed that Wolf had overlooked the convulsions because they affect, for the most part, chiefly the neck muscles. Olshausen reported a case in which he, in spite of cutting off the action of the kidneys known to be failing had seen no convulsions. For this reason it was plain that the poison of eclampsia is something different from the uræmic poison due to extirpation of the kidneys. Machenrodt had seen a similar case, and Olshausen instanced the fact that in the end stages of carcinoma which causes suppression, uræmia has been observed, but not convulsions.

For the past week there has been summer weather in Berlin, and already the waiting rooms of physicians, especially of those in the working districts, are full of children. The mortality among infants has increased greatly. At the beginning of last month, much light was thrown on this question at a meeting of the newly-formed society for combating the death rate of infants. Professor Hubner held, in this discussion, that, as a result of the falling off of nursing in Berlin in 1898, the mortality of infants had increased—and that solely because of a lack of patience and will power on the part of the mothers. While out of 1,000 living of the general population 18 die, out of 1,000 living infants 286 die. Since in the Strahlauer Foundling Asylum out of 1,000 children only 40 die, an effort to diminish the death rate of children seems wise. As a return to breast-feeding will take some time, the thing to do now is to improve the cow's milk. Ostertag briefly stated the question from the pathological point of view. The milk from diseased cows is capable of transmitting typhoid fever and tuberculosis, and may become poisonous from diseased udders, and also from medicines or food poisons contained in the milk. The milk of healthy cows may be poisonous when the milking is not done in a sanitary manner, or when the milk is not kept cool, for the bacilli which cause milk to sour are not killed by heat. Concerning the regulation of the milk supply, Engel made the statement that in Berlin over 2,000 children were injured by cheap milk. Through the action of the society many dairy companies have agreed to have their cows, stalls, etc., inspected by veterinarians and physicians. The director of railroads has been asked to have refrigerator cars for transporting the milk. Further action of the society has brought about the following: (1) Copies of regulations will be sent to dairies, physicians, infants' and children's asylums. (2) Midwives will be instructed in regard to the value of breast-feeding. (3) Notices from the society will be sent weekly to the mothers of the new-born, with a list of the inspected dairies, and with instructions regarding the care of milk and the feeding of infants. (4) A relief fund is to be established: (*a*) for poor mothers, so that by better nourishment for them, better nourishment may be assured for the children; (*b*) in order that poor people may be able to buy better cow's milk; (*c*) for providing for the destruction of the milk of diseased cows, after imposing a fine upon the dairy. (5) An agreement is to be entered into with other societies pursuing similar courses, and as many coöpertors as possible won in distant places.

How necessary the improvement in the nourishment of children is, was shown by a recent report concerning the work of the Berlin school physicians, appointed in the spring of the present year. Fifteen thousand children, recently entered in school, were examined by thirty-six physicians. Ten per cent. of all the children were found to be physically or mentally unfit, and excused from school attendance for from one-half to one year. Of these, 25 per cent. suffered from general physical debility, 16 per cent. had not overcome the results of the sicknesses of childhood, 5 per cent. had tuberculosis, 15 per cent. suffered from anæmia, scrofula, or rachitis, 10 per cent. were undeveloped mentally.

A GARDEN PARTY GIVEN BY DR. LORENZ TO AMERICAN STUDENTS IN VIENNA.

(From an Occasional Correspondent of the MEDICAL RECORD.)

Two weeks ago the Anglo-American Medical Association of Vienna—composed chiefly of American physicians who are studying in the various clinics in this Mecca of medical pilgrims—invited Prof. Dr. Adolph Lorenz to dine at the association headquarters and after the dinner give a lecture upon any subject he should elect. Dr. Lorenz accepted the invitation, and gave a lecture on Coxitis and his method of treatment. Following the lecture he spoke at length of his reception in America by the profession, and of the warm hospitality tendered him wherever he went while there. He next spoke of his—heretofore—inability to return any of that hospitality, and he took this opportunity of extending to the members of the association an invitation to come to his summer home, overlooking the beautiful blue Danube, and attend a garden party, the association being privileged to set the date which would best conform to their convenience. The association acted at once upon the invitation and voted then and there to accept the generosity of Dr. Lorenz, and Friday, June 24, was set as the date.

The weather was perfect, cool and pleasant, an ideal June day, the members of the association and their wives met at Alserstrasse station in time for the afternoon train which was to take them to Greifenstein-Altenberg, Dr. Lorenz having insisted upon bearing every expense of the trip for each of his guests. We reached Attenberg about 5:30, and were met at the railway station by the genial doctor, who greeted every one individually in the most gracious manner, then piloted us up a woody mountain road in the delicious coolness and fragrance of the shade and odors of the flowers and shrubs, to an opening commanding a most extensive view of the Danube and its valley for many miles, and of the most glorious country imaginable, mountains in every direction, many of them surrounded by picturesque old castles, and everywhere winding in and out, "like a blue ribbon," the lovely Danube.

The rare beauty of the scene cannot be expressed in mere words. It burst upon our view so unexpectedly that we were spell-bound for several moments. Soon, however, our spell was broken, for as we moved on a little further we were greeted in the warmest and heartiest manner by Madam Lorenz, wife of our noted host, who with her sisters had arranged a booth, under a huge umbrella floating from the top of which were seen the stars and stripes of our own loved country together with the orange and black of Austria. Music was also there, furnished by a company of Vienna musicians. We were invited to seat ourselves upon the grass to rest and enjoy the beauties around us, while we were served with tea, coffee, seltzer and white wine, beer, cake, and cherries. And *such* cherries! One could not find in any land more perfect fruit and more varieties. When we had enjoyed this pleasant refreshing for a time we were invited to continue our walk a little further, through lovely acres of currants, gooseberries and cherries, on down to the beautiful villa of Dr. Lorenz, which nestled about half-way down the mountain. Dr. Lorenz seemed to be everywhere, first in the fore-front, then in the rear and all along the line, and 'twas a long line, as we marched in "geese-walk" as the doctor expressed it (Gänse Marsch) about eighty of us—to his home.

It would be impossible to imagine a more cordial welcome than was accorded us, as time and again our delightful host urged us to "be at home," "be at home."

The villa consists of an original or old part and a very handsome new part. The stones of this new part have come entirely from old and noted Vienna buildings which for one reason or another have had to be taken down, and Dr. Lorenz bought them and had them transferred to his country seat, and when sufficient had been collected in this way he had the beautiful new part of his dwelling put up. The balustrade surrounding the wall and grounds came from an old stone bridge which crossed the Danube near Vienna at one time.

The ladies were taken into the private rooms of the house to remove their wraps, smooth out the wrinkles, and shake off a little of the railway dust, then went out to assemble in the palatial hall, while the doctor with the professional men ascended the stairs. The guests finding places in the beautiful gallery overlooking the hall, Dr. Lorenz stepped forward into a little balcony and addressed his guests in the warmest words of greeting and welcome. He welcomed the wives of the physicians, whom he considered as representing that type of American woman, who, as doctors' wives, shared the hardships of a doctor's life. He "welcomed the two lady doctors, whom he considered as that type of American woman who stood for woman's emancipation, and he welcomed the lady who, as neither doctor nor doctor's wife, was known the world over, and who had done so much for the profession"—Mrs. Armour—who had come out to join the Americans in their pleasant treat at his home.

He spoke again of his appreciation of all the American hospitality which he had received, and said that it gave him great pleasure to welcome us as his guests. Dr. E. L. Swift, of the United States Army, responded to the word of welcome in a very pleasing manner. After this Dr. Lorenz escorted us through his house, showing us the various apartments, the beautiful paintings from the brushes of the old masters; pointing out to us, here and there, some object of special interest. We were even

invited to inspect the kitchens, which were truly works of art, with their spotless tiled floors and wainscoting. Everything of the most approved hygienic make up, which, to quote Dr. Lorenz, "were of American-Viennese manufacture."

The house is truly beautiful. From every window one found the most glorious views of the surrounding country, while within the arrangement of the house, its furnishings and hangings, proclaimed the exquisite taste and appreciation of the harmony of color of the host and hostess.

The sixteen-months old son of Dr. Lorenz claimed considerable attention—a beautiful blue-eyed boy, strongly resembling his noted father, the perfect picture of health and happy disposition.

We were now ushered out to enjoy the beautiful grounds surrounding the house, and a little later escorted to the tennis court, which was most perfect if its kind. Here we found many tables spread with snowy linen and shining silver and flowers in profusion arranged about each place in a most artistic manner. Overhead were strung dozens of very pretty Japanese lanterns. At one side of the court was the dais upon which were seated the Viennese musicians who made music for us during the afternoon. They played and sang many very pretty selections during our meal. The supper was served in the most attractive, dainty manner, and consisted of the most tempting, delicious food one could wish for. Here again our interesting host and his good Frau flitted here, there, everywhere, among their guests, looking after each one's comfort and appetite in a manner delightful to see. Nothing was left undone that could in any way add to the pleasure and content of each and every guest. After the meal the musicians played America, whereupon we all arose and sang the national hymn right lustily. This was followed by the "Wacht am Rhein" and the Austrian national hymn. Professor Lorenz at this juncture presented each guest with a souvenir post-carte upon which was a picture of his villa, and for those who desired it, both he and his wife added their signatures.

The tables were pushed to one side and the musicians began to play dance music in such an inviting manner that the toes of the younger members of the profession could not resist, and soon the scene changed to one of frolic and fun, which lasted until about ten o'clock, when the doctor's carriages drove up prepared to take the ladies to the railway station, a short distance away, and the delightful "garden party" disbanded.

The event was certainly one in a lifetime, an afternoon and evening never to be forgotten by those of America's medical profession who were privileged to enjoy it.

The following physicians were present: W. M. Engelbach, G. A. Gardener, F. G. Harris, J. L. Jacques, O. H. Kraft, W. H. Lamborn, G. P. Marquis, F. R. Morton, Brown Pusey, G. W. Parker, H. Schafer, and J. I. Wernham, of Illinois; A. E. Austin, D. W. Clark, F. J. Hurley, D. J. McSweeney, A. E. St. Clair, of Massachusetts; H. L. Aller, F. Goldfrank, Mary Sutton Macy, Isabelle Thompson Smart, A. W. Booth, of New York; E. S. Geist, D. N. Lando, H. L. Williams, of Minnesota; Francis W. Alter, H. W. Ely, H. H. Wiggers, Tubman, of Ohio; H. L. Akin, E. C. Henry, S. J. Jones, of Nebraska; A. L. Mackenzie, E. A. Mallon, H. G. Wertheimer of Pennsylvania; E. D. Clark, F. N. Hibben, of Indiana; Louis Rassieur, F. L. Stüver, of Missouri; E. D. Chipman, Chas. Fitzgerald, of Connecticut; E. F. Dodds, L. H. Fligman, of Montana; H. J. Schlageter, A. S. J. Smith, of California; J. J. Sullivan, New Jersey; E. Van Hood, Florida; S. K. Simon, Louisiana, C. E. Zerfing, South Dakota; Bernard J. O'Conner, Kentucky; A. C. Behle, Utah; R. P. Daniells, Wisconsin; R. H. Dean, Iowa; J. H. Davis, Colorado; A. W. Ives, Michigan; C. A. Lilly, Kansas; Walter Luttrell, District of Columbia; E. L. Swift, United States Army; A. H. Bennett, Adelaide, Australia; W. H. Goodden, Bristol, England; A. S. Wilson, Aberdeen, Scotland.

PHTHISIOPHOBIA.

To the Editor of the Medical Record.

Sir: I have only lately read the very able plea for "Justice to the Consumptive" made by Dr. S. A. Knopf in your issue of January 2. In quoting me as opposed to the Goodsell-Bedell law, I am sorry to confess that Dr. Knopf does me too much credit. My opposition to this bill was solely on account of some details that seemed to me to make its operation impracticable. I am the rankest kind of a phthisiophobe, though no longer of an age or build to have any personal fear of the disease. Statistics show that, excluding deaths from violence and old age, tuberculosis kills about a quarter of us all, hence its control has just about one-third of the importance of all other diseases together. A parasitic disease which has no necessary intermediate host, which requires no peculiar method of implantation, and which is not synchneident, can, according to our present knowledge, be controlled satisfactorily only by the general principles of quarantine.

It is straining at a gnat and swallowing a camel to subject patients with acute exanthematous diseases—which are all semelincident—to the hardships of quarantine and to allow tuberculosis patients, in the stage of discharge, to go free. I believe that whatever diminution in the prevalence of tuberculosis has thus far occurred, has been due mainly to professional and lay phthisiophobia, and not to any considerable degree to condemnation of cattle, improvement of resisting powers, or therapeutic measures against the existing disease. I believe, also, that just as leprosy was removed from most European countries in the middle ages by enforced segregation, so enforced governmental segregation in sanatoria is the only promising method of dealing with the modern problem of tuberculosis.

With regard to the exclusion of tuberculous immigrants, I agree with the Surgeon-General of the U. S. Public Health and Marine Hospital Service that no immigrant should be admitted who is any way a menace to our own country. Indeed, I would go much further, and admit only a very superior class of prospective citizens. In other words, when the matter concerns the general welfare of my countrymen, I would be absolutely cold-blooded and selfish.

A. L. Benedict, M.D.
156 West Chippewa Street, Buffalo, N. Y.

INFECTIOUS DISEASES IN PERU.

(From Our Special Correspondent.)

Arequipa, May 31, 1904.

The bubonic plague seems to have taken a permanent hold of Lima and Antofagasta. It is probable that from these centers it will extend to the rest of the coast. In Lima the cases are not numerous and are of a comparatively mild character, many of those attacked recovering and the infectivity being low.

Here we are having smallpox and a few cases of diphtheria. The former, when treated early by touching the papules with carbolic acid and also giving the same remedy or salol internally, generally doing well and leaving little disfigurement.

Diphtheria, if treated early by antitoxin and a mixture of tincture of chlorate of iron, solution of ammonium acetate and potassium chlorate taken in lemonade, and the throat swabbed out with peroxide of hydrogen and glycerin, is not very fatal. The infection of diphtheria may last for a long time.

I saw in consultation this month a boy of eight years, suffering from diphtheria. More than two and a half years previously I had seen his aunt with diphtheria in the same house. There was no other known or suspected source of infection. The house had been shut up after the illness of the aunt.

Progress of Medical Science.

The Boston Medical and Surgical Journal, July 7, 1904. **Aciduria (Acetonuria) Associated with Death after Anæsthesia.**—E. G. Brackett, T. S. Stone, and H. C. Low report a number of cases which present certain features in common: Vomiting associated with collapse; a very weak and rapid pulse; an absence of fever until just before death; cyanosis in the fatal cases causing extreme dyspnœa; apathy and stupor alternating with periods of restlessness at first, but in the fatal cases gradually deepening into coma and death; and the presence of acetona in the breath and urine. In six cases the symptoms came on without operation. In three of these cases the symptoms came on the day after entrance, and in one two days after. In one case the symptoms came on after the child had been in the ward for four weeks and was up and about. In seven cases the symptoms followed operation. Three of these patients died, four recovered. In the four milder cases the symptoms came on between 12 and 24 hours afterward. In the three fatal cases, alarming symptoms came on after about 12 hours, but in none of the cases was the recovery from the operation quite normal. Those children in whom the symptoms were severe were of high-strung, nervous temperament. The symptoms coming on after operation were usually more severe than those coming on without operation, although there was one rapidly fatal case in the latter group. Death in the fatal cases occurred from 12 to 36 hours after the onset of the symptoms. It seems to be due in some cases to a lack of oxygen. Eleven cases showed acetonuria, and only two did not show diacetic acid in the urine, and in one of these the test was not made for it. The only marked anatomical lesion found in the four autopsies was the extreme fatty degeneration of the liver and the muscles. From the study of these

cases it can be stated that the symptoms are not the result of anæsthesia, operation or shock, unless in the presence of certain underlying causes still undetermined. Especially in nervous, high-strung children, the confinement, changed habits, changes in diet, homesickness, dread of operation, anæsthesia, and the operation itself may lead to changes in metabolism which have hitherto not been taken into account. Greater attention should be paid to the temperament of children entering a hospital. The absence of any gross evidence of a pathological condition may not constitute immunity from the danger of acetonuria, and possible death after operation. Caution should be paid to those cases in which the presence of a fatty liver is suspected. Special care should be exercised in those cases which show extensive degenerative changes, such as is seen, for example, in extensive infantile paralysis.

Journal of the American Medical Association, July 9, 1904.

The Crisis and Treatment of Pneumonia.—W. J. Halbraith does not offer his plan of treatment as a specific but claims it has materially lowered his death rate. The first attention to be rendered in the ordinary cases is a warm bath and a saline cathartic. The indications governing the administration of quinine and iron are as follows: When the temperature has reached 105°, or over, 60 grains of quinine sulphate is to be administered as the initial dose, followed in one hour by one-half this amount, or 30 grains, and in another hour by one-half the latter dose, or 15 grains, at which time the author begins the administration of tincture of iron in doses ranging from 7 to 15 minims, depending on the stage of the disease and the condition of the heart. If he sees the patient on the first or second day of his attack, he usually begins with 10 minims of tincture of iron, increasing it one or two drops, or even more, each day up to the sixth or seventh day, unless the pulse remains strong and full. He does not believe in giving quinine in small and repeated doses during the active stages. When the temperature is 104° or over he gives 50 grains of sulphate of quinine and follows the same course as given above. When the temperature is 103° he gives from 30 to 40 grains, and follows the same course. During convalescence he has found iron, quinine, strychnine, guaiacol, and cod-liver oil of value. What has served him best are thorough ventilation and sunlight, with plenty of milk, eggs, and beefsteak.

The Yellow Fever Epidemic of 1903 at Laredo, Tex.—G. M. Guiteras reviews his experience in this epidemic, and draws the conclusions that the results obtained through the efforts to combat the epidemic at Laredo demonstrate that the *Stegomyia fasciata* is the only means of transmitting the disease. Oiling all water containers and deposits of stagnant water was completely successful in preventing the reproduction of mosquitos. Inasmuch as the *Stegomyia fasciata* can become infected by biting the patient during the first three days of the disease only, it is of vital importance that cases of fever be reported at the earliest possible moment, so that they may be screened. It is impossible to obtain good results without a mosquito-proof yellow-fever hospital. The difficulties of handling an epidemic are increased when such outbreak occurs on the frontier. Arrangements should, therefore, be entered into by treaty with contiguous foreign countries, so that sanitary measures may be carried out jointly by the countries interested. Those residing within the sphere of influence of the *Stegomyia fasciata* should be taught through the medium of the public press to protect themselves against yellow fever by destroying the means for the propagation of the mosquito and by protecting themselves against the mosquito by efficient screening. If the first case presenting the slightest suspicious symptoms of that disease were promptly made public, and the proper modern precautions taken, there would be no danger of the disease spreading.

The Medical News, July 9, 1904.

Yohimbine; Its Use in the Treatment of Eye, Ear, Nose, and Throat Diseases.—J. H. Claiborne and Edward B. Coburn have tested the local anæsthetic properties of yohimbine. They regard it as inferior to cocaine in all operations upon the eye on account of the congestion produced by it. For the examination of the nose it was not as effective as cocaine, because the contraction caused by it was not so marked. It has been found useful in ear and nose work. Its advantages may be summed up as follows: It is nontoxic; there is long duration of anæsthesia after its use; it does not markedly contract the tissues; the taste is only slightly bitter; it does not cause unpleasant contraction of the throat and mouth. Its disadvantages are that it does not keep well; it does not contract the tissues; after its use there are hyperæmia and hemorrhage after operation; salivation is caused by its use.

The Theory of Mutation in Its Relation to Medicine.—Jonathan Wright declares that evolutionary science is drifting in the direction of spontaneous generation. He believes that the theory of mutation in biology, if it is settled in the affirmative, will have a very important bearing upon our knowledge of the etiology of disease. The author recalls the declarations of De Vries, an Amsterdam naturalist, that there are certain jumps in the life history of species, which are really the origin of species. He has specially studied the primrose in this regard, and has observed changes which he calls mutations, and these changes were so sudden and profound that he has come to believe that all species at some time in their life history exhibit an excessive instability from which new and distinct forms arise. The writer does not see how this idea in any way upsets the fundamental idea of Darwin. He believes that "the theory of mutation" is important to the conception of microbic disease. In the decades preceding the middle of the last century, it was the common belief that from time to time the character of certain diseases changed in their clinical manifestations; that, for example, during a longer or shorter time, pneumonia presented sthenic types, suitable for bleeding, followed by asthenic types when such procedures were disastrous. Again, diphtheria is not sufficient to account for the severity of the cases of throat inflammation with which Hippocrates had to do. In the history of smallpox and phthisis we know with what rapidity early races have been all but exterminated by these diseases. Ancient books give no record of many a scourge which has since worked havoc among civilized nations. The writer suggests that we may suppose that many diseases as the resultants of primordial changes in the cell and the microphyte entered in the dark ages upon a period of mutability similar to the primrose in Holland after it was carried there from America in 1613. In the pre-Renaissance, diseases seem to have originated with a shock or jump, since that time being more or less constant except for the minor changes in type. Just as with plants, they may have been formed from a mother disease which may still exist. It is in the period of upward of 1000 years after the fall of ancient Rome that we seek the origin of smallpox, scarlet fever, measles, whooping-cough, influenza, possibly even syphilis. The newer the disease, the more limited its range among animals. Phthisis and pneumonia are coeval with the dawning of the history of man; diphtheria can be traced back to the Babylonian Jews. Reports of the influenza were the first to emerge from the obscurities of the dark ages. These diseases are widespread in the animal world, but syphilis, smallpox, whooping-cough, scarlet fever, measles, of later historical mention, are also markedly less widespread in the animal kingdom. As to spontaneous generation, the writer does not believe that the phenomena, both biological and historical, of microbic disease necessitates its assumption, and we have little ground for this theory in facts hitherto presented. He believes that whatever may be the trend toward this view, the labors of Löwenhoeck, Spallanzanni, Virchow, Tyndall, and Pasteur, have definitely thrown the burden of proof on its future advocates.

American Medicine, July 9, 1904.

Gangrene of the Finger Caused by Carbolic Acid.—George Erety Shoemaker believes that not enough attention has been given to the danger of producing gangrene by the use of even comparatively weak solutions of carbolic acid applied as a dressing for a number of hours. It has been proved that the use of full strength of the acid is not necessary to produce gangrene. In using dilute solutions on a finger, it seems to be necessary for the production of gangrene that the entire finger be surrounded by the solution and be tied up in it for not less than 24 hours. The literature furnishes a number of such cases. In most cases the effect is painlessly produced by a dressing kept moist for about 24 hours, and the strength of the solution employed may be from 1 per cent. to 5 per cent. The result is not due to tight bandaging; the dilute solution is capable of producing the effect, and gangrene does not always follow the application. It has been shown experimentally that the death of the part is due to chemical action and that other diluted chemicals may produce the same effect if applied by a moist compress for 20 to 24 hours. The same solution does not always produce the same result. Caution in regard to this matter is especially necessary in dermatology and in minor surgery.

Concerning the Invasion Period of the Malignant Estivoautumnal Tertian Malarial Parasite.—Thomas W. Jackson states that it seems not at all unlikely, as contended by a number of observers, that the period of incubation of malarial fevers is a variable one, and that the variation is an extreme one, depending upon certain ill-understood conditions of the subject of inoculation, and the stage and variety of the inoculated parasite. The writer reports eighteen cases, however, which seem to support the propo-

sition that, under the same conditions, the period of incubation for a number of individuals inoculated by mosquitos with the same malarial parasites, at approximately the same time, varied but slightly. After a careful study of these cases, the writer feels justified in stating that: In an epidemic of eighteen cases of estivoautumnal fever (of the malignant variety) which occurred in Troop A, Sixth U. S. Cavalry, in the Philippine Islands in April, 1902, the invasion or incubation period was between ten and eleven days. The author believes that the inoculating mosquitos in this epidemic obtained the malarial parasites probably from native Filipinos who had previously been in the vicinity, it being a fact well known and proven that the natives suffer extensively from malarial disease, in both its active and latent forms.

The Treatment of Gallstones Found as a Coincidence in Abdominal or Pelvic Operations.—John G. Clark presents the following conclusions: (1) The usual statement that 95 per cent. of gallstones produce no symptoms is fallacious because it is drawn from an autopsy and dissecting-room statistics. (2) Recent researches point very strongly to the bacteriological origin of gallstones. (3) Bile is not bactericidal, for in the majority of cases of cholelithiasis microorganism of a more or less pathogenic nature are discovered. (4) Under these circumstances, many more or less vague symptoms attributed to gastrointestinal or general constitutional disturbances may arise from toxins elaborated around these foreign bodies in the gall-bladder. (5) All clinicians admit that there is a wider hiatus in the clinical symptoms between the early formation of gallstones and the so-called classic attacks of biliary colic with jaundice. (6) Abdominal surgeons should make a most careful record of all gastrointestinal or hepatic symptoms and other vague epigastric pains and associate these with an examination of the gall-bladder with a view to establishing a further link in the symptomatology of cholelithiasis. (7) As cholelithotomy in a large series of cases has been attended with less than 2 per cent. mortality, the coincident removal of gallstones with some other abdominal operation is not a hazardous undertaking. (8) In the author's cases, more than 50 per cent. have shown symptoms which could be unquestionably or with great assurance attributed to the presence of gallstones. (9) This coincident operation should be dictated by the most careful judgment, for if the patient is in a critical condition from a prolonged operation, or the primary operation has been a septic one, this extra operation may be attended by serious results.

New York Medical Journal, July 9, 1904.

The Home Treatment of Pulmonary Tuberculosis.—E. Fletcher Ingals says that in at least two-thirds of the cases of pulmonary tuberculosis recovery ensues, for statistics showed that only 12 per cent. die of this disease, and autopsies showed that in 25 per cent. recovery from it had taken place. He believed the so-called antiseptic treatment was often beneficial, the open-air treatment equally so, and forced feeding was more important than either, while tonics, digestive agents, and anodynes that did not interfere with the ordinary functions of the body were also of much importance All of these should be combined and the patient placed in a good climate; when the latter was impossible much could be done at home. He then reported a case in which open air living could not be secured, and which illustrated the effects of home treatment, with as liberal feeding as possible, aided by tonics and digestive agents, anodynes to prevent excessive cough, and antiseptics in large doses. A second case was cited to illustrate the benefits of the open-air treatment.

Effects of the Dry Carbonic Acid Gas Bath on the Circulation and on the Diseased Heart.—Achilles Rose gives a description of his bathtub, and since he could not find in the literature a record of the effects of the dry carbonic acid gas bath on the number of pulsations, one was presented from his case book. The rapidity of the whole blood circulation in the superficial vessels increases during the bath, and this was shown by the increased strength and volume of the radial pulse. The pulse of the bather, within a few minutes after having entered the bath, resembles a pulse stimulated by alcohol.

The Unhealthfulness of Noise.—J. A. Guthrie, U. S. N., asks what objections could be made against the statement that noises create a disturbance of the nervous elements to such degree that they should be given a place in the category of disease causations? When a healthful condition of the nerve exists, we bear a greater amount of nervous shock with impunity; but by frequent repetitions of this shock, we are rendered less able to withstand the resulting jar The author instances certain facts to prove that sudden noise is disconcerting.

The Lancet, July 2, 1904.

The Treatment of Hemorrhoids and Allied Conditions by Oscillatory Currents of High Tension.—T. J. Bokenham bases his experience on 118 cases. It seems to be admitted generally by all who have put matters to the testt hat (1) Doumer's method is striking and quickly successful in cases of sphincter fissure and in healing the small fissures so often associated with hemorrhoids; (2) it is valuable in relieving pruritus ani associated with similar conditions; (3) its value in the treatment of external and internal piles is greatest in early cases which do not exhibit excessive hyperplasia and thickening of the tissues; (4) in cases of very old standing accompanied by much hypertrophic change and infiltration of the hemorrhoidal tissues the treatment gives poorer results, and at best has to be persevered in for long periods.

Accidental Vaccina of the Nasal Cavity.—W.H. Bowen reports such a case occurring in a woman who was nursing her baby, who had been successfully vaccinated. The mother had not been vaccinated since she was a baby Anyone who has watched a baby, either taking the breast or being carried in the mother's lap, remembering the restless way in which babies "claw" at everything about, and with special frequency the mother's face, will readily understand the ease with which inoculation was brought about Of forty-six other cases of accidental vaccination which the author has found reported, thirty-one were on the face, one on the tongue, eight on the trunk, and four on the limbs. The only other case of accidental vaccination of the nasal cavity was reported in the *Birmingham Medical Review* for 1903.

Use of Sodium Arseniate Hypodermically in Tsetse-fly Disease in Cattle.—Edward J Moore says that some months ago the Government of Southern Nigeria established an experimental farm with the intention of teaching natives to use cow's milk as an article of diet for their children and thereby to put a natural check on twin murder by removing the reason on which the practice is based, viz., the inability of most ill-fed women to rear two children. Twenty-two cattle, principally West Indian, were established there and, after one month, began to show the first signs of the disease. Fowler's solution of arsenic was administered in one-drachm doses three times daily without improvement. Larger doses of one ounce were attempted, but had to be discontinued because they increased the already existing tenderness of the mouth to such an extent that the animals refused to take food and their general symptoms became aggravated. Under these circumstances he prepared a one-per-cent. solution of sodium arseniate, rendered slightly alkaline, and selecting the worse case injected one ounce of this hypodermically on two occasions at an interval of one week. The beneficial effect was marked and immediate.

Non-flagellate Typhoid Bacilli.—J. W. W. Stephens' method for staining flagella with silver was a modification and simplification of van Ermengem's method, and he had constantly got positive results with it, so that he felt secure in describing it last year. Shortly after having done so he was surprised at being unable to stain flagella in a culture of typhoid bacilli which he had used for demonstrating the method. Further experimenting made him feel justified in concluding that his failure to stain the old cultures was due to the fact that there was no flagella there to stain. He therefore concluded that we may have non-flagella typhoid bacilli. The bearings of this observation may be of interest. (1) It may be necessary to pass a bacillus, *e.g.* Bacillus dysenteriæ (Shiga), through an animal or to examine freshly isolated bacilli before we can be quite certain that they do not normally possess flagella. (2) The typhoid bacilli which were examined above, and which he believed did not possess flagella, were said to "react normally" in typhoid agglutination tests. If this was so then flagella could not be an essential factor in this phenomenon.

British Medical Journal, July 2, 1904.

Pneumococcal Appendicitis and Peritonitis.—Lauriston Shaw and Herbert French describe the case of a girl aged eighteen years who, when she was admitted to the hospital, was too ill to operate on. She died a few hours after admission. Autopsy seemed to disclose the condition of primary acute appendicitis with general peritonitis. Cultures taken from the appendix and from the peritoneal lymph yielded an almost pure growth of pneumococci. The case is apparently one of primary pneumococcal appendicitis, associated with pneumococcal peritonitis, and the authors think it worth recording.

The Leishman-Donovan Body in Ulcerated Surfaces.—Patrick Manson and George C. Low report that in the infiltrated areas of a small intestinal ulcer, and in an ulcer from the large intestine, Leishman-Donovan bodies, few in number but unmistakable, have been found.

They were inclosed in cells. In sections of liver, spleen, and lymphatic glands the position of those bodies is doubtless, in the majority of instances, intracellular. The writers have never seen the parasites in the red blood corpuscles in sections or otherwise. Wright and James have found these bodies on a similar organism, in ulcers of the integuments (Oriental sore), Christophers in intestinal ulcers. The writers ask if failing the discovery of any other means of exit from the body, may it not be that the normal route of escape from the parasite is by an ulcerated surface? It is seen from these observations that these parasites may escape by the intestinal canal.

Intravesical Separation of the Urine from Each Kidney.—B. G. A. Moynihan speaks of two methods of obtaining the urines from each kidney separately—by catheterizing the ureters, thus obtaining the urine before it has entered the bladder, or by creating a septum in the middle of the bladder in such a way that the urine from each ureter is confined to its own side of the bladder from which it is drawn through a small catheter. For the last method, the first perfectly efficient instrument was made after some modifications of the original pattern by Luys of Paris. It is made so that a thin india rubber sheathing is raised up, forming a septum. The lateral pieces, fitting on to the sides of the central piece, consist of two catheters having several eyes. Each catheter drains its own side of the bladder after the septum has been created. Another perfectly satisfactory instrument is that of Cathelin of Paris. This has a leaf or septum of india rubber. This instrument presents no difficulty in the introduction, but if the bladder is small and the septum is pushed fully into the bladder it will twist to one side, and the partition will be defective. Luys' instrument is of no value unless the bladder be fairly normal in size and position. The writer is at present in favor of the use of Luys' instrument for the female, and of Cathelin's for the male, though he adds that a more extended experience may modify his opinion.

Pads upon the Finger Joints and Their Clinical Relationships.—Archibald E. Garrod defines these pads on nodules as excrescences, which are almost confined to the dorsal aspects of the interphalangeal joints of the proximal row, and are only very rarely seen upon the terminal joints of the fingers. There is no striking symmetry in their distribution. They vary in size from that of split peas to that of the halves of hazel nuts. They are usually central in position, though they may incline to one or other side of the joint. Sometimes the lumps are quite painless, but more often pain is complained of, especially when the fingers are flexed. They are doubtless mainly composed of fibrous tissue. There does not appear to be any connection between these pads, and any of the morbid conditions which are usually grouped together under the names of rheumatoid or osteoarthritis. Two elderly patients, however, did have well-marked Heberden's nodes in addition to the pads. There is doubtless an intimate connection between Dupuytren's contraction and these pads. At least six out of twelve patients showed Dupuytren's contraction. This might be styled a paragouty lesion. But the connection of these pads with gout is clearly less obvious than that with Dupuytren's contraction. The writer knows of no plan of treatment which is of any avail in reducing the size of the pads. A patient who develops them in early life appears to be liable finally to develop Dupuytren's contraction of the palmar fascia, but aside from this they do not seem to possess any grave prognostic significance.

Deutsche medizinische Wochenschrift, June 23, 1904.

Scapular Crepitus.—Axmann describes an instance of this rare condition in a boy of eighteen, in whom a crepitus gradually developed under the right shoulder-blade. Otherwise the patient was normal and in good health. On lifting the shoulder the crackling sound could be heard at a distance of several yards. Passive motion fails to elicit the noise and muscular action seems to be requisite. A Röntgen ray picture failed to show any abnormalities. As the patient displayed no symptoms requiring alleviation, no treatment was instituted. Kuttner, in his report of twenty-two cases thus far noted, calls attention to the following etiological factors: bony deformities in the scapula or thorax, the result of tuberculosis or syphilis ankylosis in the shoulder-joint; paralysis with muscular atrophy; abnormal synovial diverticulæ. None of these could be demonstrated in this particular patient.

A Case of Senile Dementia Accompanied by Contracted Kidneys.—G. Lomer reports a case in a man of fifty-six in whom these two conditions were closely associated and probably dated from the same cause—the presence of an arteriosclerosis. The differential diagnosis was a difficult matter, for during the entire period of observation, no specific uræmic symptoms, such as vomiting and convulsions, ever appeared. The urine showed a high specific gravity and the amount of albumin by Esbach's test, was 13 per cent. An albuminuric retinitis was not present at any time. The arteriosclerosis could be accounted for by a history of both alcoholism and syphilis, and there was also a possibility that an attack of meningitis at the age of thirty may have weakened the cerebral vessels. A noteworthy point in this case was the early appearance of the dementia, which is usually not observed until about sixty-five. The patient was favorably influenced by sanatorium treatment, and in a few months the albumin dropped from 13 per cent. to 2.5 per cent. The psychical disturbances were also improved. The prognosis is very uncertain, however, as to the original disease; the arteriosclerosis will resist all efforts at a cure.

Berliner klinische Wochenschrift, June 20, 1904.

Destruction of the Ear Drum by Lightning.—K. Burkner calls attention to the rarity of injuries to the auditory apparatus by lightning, of which only a few cases have been reported. The author's patient was a boy of eighteen, who was in a tower which was struck by lightning. An aural examination showed an extensive tear in the membrane, part of which was folded back over the handle of the malleus. That the perforation did not occur as the result of a fall, to which the boy was also subjected, is shown by its contour, the slight amount of hemorrhage, the absence of symptoms in the labyrinth, and the fact that the only other injuries on the head were the burns caused by the flash. It remains an undecided question, however, whether the laceration was due directly to the electric spark or to the shock accompanying the sudden electrical discharge from the body.

The Value of Water in Disease.—E. Homberger discusses the importance of a plentiful administration of water in disease processes, especially those accompanied. By this method the most distant cells may be reached and restored to their normal physiological condition. As the conception of a cellular pathology also requires a cellular therapy, this agent seems to be the most rational means to attain the end. During the course of a fever, there is an insufficient quantity of water present in the system, and this the body is slow in giving up, resulting in a diminished quantity of sweat and urine. Perspiration, the author claims, is only restored when the temperature of the body begins to drop and the superfluous water is no longer needed. This is contrary to the usually accepted opinion. Although water is by no means a panacea, it is of great value in all those diseases in which the toxins have circulated in the blood for a considerable period of time. But when these rapidly leave the circulatory system and unite with the cells, this agent is of little avail.

Münchener medizinische Wochenschrift, June 21, 1904.

Herpes Zoster in Croupous Pneumonia.—Riehl observed, among 481 cases of croupous pneumonia, that a well-localized herpes zoster developed in 129—about 27 per cent. This, however, is considerably less than the number stated by other authors, who report about 40 per cent. The affection seems to afflict the male sex more often than the female, and usually appears on the third or fourth day of the disease. The author calls particular attention to the localization of the eruption, which is most marked over the distribution of the second and third branches of the trigeminus, and especially the infraorbital nerve. It is rarely found in the area of the first branch, and only on the neck, trunk, or extremities in exceptional instances. Pneumonias in children and the aged usually run their course without any herpes eruption. Mild cases of pneumonia are characterized by an extensive eruption, while the severest cases are most always free from this complication.

Orthodiagraphy and Percussion of the Heart.—Schule has studied, for purposes of comparison, these two methods for mapping out the boundaries of the heart. The former, in which the determination is made by means of the *x*-rays, was introduced by de la Camp and Moritz, and has also been used by a number of other observers, all of whom are in agreement as to the results obtained. The authors find that the cardiac area as mapped out by the ordinary methods of percussion does not exhibit any appreciable variations from that determined by the use of the *x*-rays. Percussion need not be superseded by the rays, but in doubtful cases the ideal procedure would consist in a verification of the results obtained by percussion, by an examination with the *x*-rays. The latter is undoubtedly a most efficient secondary diagnostic aid.

An Unusual Injury to the Orbit.—F. Salzer reports an interesting case in which a bit of leather whip lash about 1½ cm. long remained imbedded in the orbital cavity for a period of three weeks without being discovered. The man had been struck in the upper lid, which pre-

sented a small wound. The eye was much contused but the wound healed promptly. Suppuration followed later on, but the probe failed to detect any foreign body in the discharging sinus until about a week afterward, the very much softened fragment of leather was extracted from the wound. The author accounts for its entrance by the fact that on the day the injury occurred, the weather was very cold and the leather was frozen stiff and probably covered with ice, which faciliated its entrance into the orbit. The patient made a good recovery.

The Relation of the Neutrophile Leucocytes in Infectious Diseases.—J. Arneth claims, as a result of extended investigations, that the progress of the disease process may be rendered demonstrable to the eye by the morphological changes in the neutrophile leucocytes. To some extent each type of infectious disease was associated with definite changes—in one type they were well marked, in another less so, and in a third, scarcely noticeable. The same author now presents some further types which he has studied, including cases of miliary tuberculosis, traumatic tetanus, varicella, meningitis, diffuse peritonitis, purpura, sepsis, typhoid pneumonia, hepatic abscess, and hydrochloric acid poisoning. The neutrophile leucocytes are divided into five classes, according to the division of the nucleus into one, two, three, four, five, or more parts. In the case of miliary tuberculosis, which ended fatally, almost all the cells belonged to classes one and two. This he interprets as meaning that the body is only supplied with only the younger and immature elements for its protection. The older classes, containing a more divided nucleus, being practically wiped out. This picture grew increasingly worse toward the end. Very few morphological changes were noted in the leucocytes from the case of tetanus, the only difference noted being the increased percentage of neutrophiles in proportion to the total number of leucocytes. In a case of smallpox which recovered, the maximum change was noted in the beginning, and as the patient got better, a gradual return to the normal took place. The two cases of suppurative meningitis presented an anisohypercytosis, and changes in the neutrophiles were very limited. The remaining cases also showed characteristic changes, and the author hopes to have his findings substantiated by other observers.

French and Italian Journals.

Continued Slow Pulse; Osseous or Calcareous Degeneration of the Myocardium.—M. H. Dufour observed a patient whose pulse was from 36 to 40 a minute. Autopsy revealed a calcareous or osseous degeneration of the myocardium, remarkable for its extent. It involved the mitral valve and formed a tumor the size of a nut, which was encysted by a zone of tissue which appeared to be fibrous. There were several superficial areas of softening in the brain, which accounted for the attacks of apoplexy from which the patient had suffered. Examination of the bulb and pneumogastrics was negative.—*Le Bulletin Médical*, June 11, 1904.

Considerations of 640 Cases of the Widal Reaction.—E. Cler. C. Quadrone, and A. Ferazzi have recorded 640 cases in which the Widal reaction was found in the laboratories and hospitals of Florence in 1902–03. They found the reaction of agglutination in various non-typhoid febrile diseases, but not in a less dilution than 1–20. They also found it in some non-febrile affections. In 166 cases of true typhoid they found the Widal reaction present. They conclude as follows: (1) Serum of persons not having typhoid may produce agglutination like that of Eberth's bacillus. (2) This action if observed in a high grade of dilution, less than 1 20, may be ascribed to the presence of the Eberth bacillus in a latent or pre-typhoid infection. (3) In a dilution greater than 1–20 it has a diagnostic value for typhoid. Absence of this reaction does not exclude typhoid, and is due to the formation in the blood of anti-agglutinins.—*Rivista Critica di Clinica Medica*, May 14, 1904.

Congenital Cyanosis.—Méry states that the congenital cardiac lesion which occasions the cyanosis consists of two principal lesions: Stenosis of the pulmonary artery; interventricular communication or Roger's sickness. The writer describes three cases which he has lately observed, all of which showed the same general symptoms. When the child cries, a crisis of paroxysmal cyanosis is precipitated. These crises occur two or three times a day, lasting from five to ten minutes, accompanied by acute dyspnœa and convulsions. Auscultation showed a prolonged systolic murmur in the middle cardiac region. In one case the extremities were always cold. Sometimes the axillary temperature drops from 2 to 3 degrees. The blood corpuscles are greatly increased in number. The liver and spleen are not increased in volume. The prognosis in these cases is very bad. The children are carried off by their cardiac troubles or by pulmonary tuberculosis. Treatment should consist chiefly in observing for these little patients the general laws of hygiene. They should be guarded from all emotion.—*Journal des Praticiens*, June 11, 1904.

Contribution to the Pathology of Tabes Dorsalis—Carlo Fantiggia states that most modern authors regard progressive paralysis and tabes dorsalis as the result of the same pathological process taking place in different anatomical regions, in the cortex of the frontal lobes of the brain in paralysis, in the spinal cord in tabes. Or we may have a mixed form, involving both parts and giving symptoms of each disease. Many consider these diseases as a toxic effect of syphilis, yet independent of syphilis itself. Mercurials do not give good results in tabes, and in some cases give distinctly bad ones. These diseases may be the result of poisons produced in the system, resulting from the same cause as syphilis, yet which are not affected by mercury, as the late paralysis of diphtheria, is not improved by antitoxin. Such poisons may be elaborated by other diseases than syphilis. The author cites a typical case of tabes dorsalis with apoplectiform attacks.—*Gazzetta Medica Lombarda*, May 23, 1904.

Biological Action of the Sedative Application of the Positive Pole as Produced by the Different Apparatus Used for Producing the Continuous Current.—Giorlama Mirta considers the stabile application of the anode over the seat of pain as of great value in treating painful affections of the nerves and paræsthesiæ. The failures in this method are due to the source from which the electricity used is derived. The current must be perfectly even, because the slightest oscillations and variations in strength stimulate the nerve treated. The application must begin gradually, with a very slowly increased current, and must cease in the same way. The effects are different according as the current is derived from a source whose voltage is small, or one whose voltage is great, but reduced by the interposition of great resistance. If the electric light current is used there may be various sources of the current, and they may vary at different times of day. When produced by a dynamo, the current has slight oscillations and variations that, although not detected by measuring instruments, are still felt by the more delicate nerves of the human body. The author uses only the Leclanché cell, or those of Ringer.—*Giornale d'Elettricità Medica*, May and June, 1904.

The Functions of the Kidney and Renal Insufficiency.—Cauterman, after considering this subject from various points of view, speaks of the treatment of renal insufficiency. He states that the exact treatment of this affection is based upon an intimate knowledge of the phenomena of this condition. The indications are various. One should avoid introducing into the organism, in the form of food and drink, substances with a high molecular concentration, rich in toxins, rich in chlorides. Fermentation and abnormal alterations of food ingested should also be avoided, for a food, harmless in itself, can become irritating and injurious, under certain conditions, such as stagnation, etc. The compensatory organs of the kidney should be carefully watched—the liver the intestine, and the skin. The drugs recommended for this condition should be carefully studied. And all of the mechanical means known for diminishing the tension of fluids in Bright's disease should be considered.—*Annales de la Société Médico-Chirurgicale d'Anvers*, March–April, 1904.

Radiotheraphy in the Treatment of Tumors of the Stomach.—Doumer and Lemoine have treated twenty gastric tumors by this method. Of these they believe that three cases were completely and finally cured. A fourth is on the way to recovery, while a fifth in whom the improvement was very rapid, and in whom the tumor completely disappeared, has had a relapse that does not yield to treatment. In the other cases the tumor has had a variable course according to the case. In all of the cases without exception this treatment has caused the disappearance of, or great diminution of, pain, and this from the first application. Vomiting has ceased or has greatly diminished, and feeding has thus become much easier. Without any doubt the general state has been greatly improved. Doumer and Lemoine conclude that there are certain forms of gastric tumors in which this treatment has worked a complete cure, lasting so far for a year and a half in several cases, and other forms in which the treatment has been incomplete in its effects, destroying the tumor in its original place, but not hindering its extension to neighboring parts and its metastases to distant parts.—*Le Bulletin Médical*, June 15, 1904.

Extirpation of Cancer of the Kidney.—M. A. Malherbe described this case which came under his observation. The patient, a man of forty-six years, was suffering from hæmaturia in September of 1903. From that time he

lost considerable flesh; he was yellow, and had a cachectic look. The urine seemed normal, and was very abundant. On palpating the right flank, a tumor was clearly felt. It reached down to the iliac fossa, and was quite movable. In spite of the cachexia of the patient, as he had nothing to lose and everything to gain, Malherbe decided to operate on February 13, 1904. There was little hemorrhage, but an injection of artificial serum was given. The affected kidney weighed 390 grams. The two poles were comparatively healthy, but on the posterior surface at about the union of the lower and middle thirds, was a large tumor. On section the cortical substance looked almost as much like tuberculosis as it did like a new growth. But in the pelvis the new growth was very evident. Histological examination showed the tumor to be alveolar epithelioma or cancer of the kidney. At the beginning of March the patient began to improve slightly, but still had a cachectic aspect. Finally, in April, the improvement was decided. He ate very well, and increased in weight. About April 20 he left the hospital in a very satisfactory condition.—*La Médecine Moderne*, June 15, 1904.

Peroxide of Magnesium in the Treatment of Acid Diarrhœa of Adults.—Betherand and Rene Galtier declare that the acid diarrhœas seem to them to be the only type that indicate treatment by means of peroxide of magnesium. Peroxide of magnesium is decomposed only in an acidi medium. In the stomach, hydrochloric acid or the fermentation acids decompose the peroxide into chloride of magnesia and hydrogen peroxide, and the latter is finally separated into water and oxygen. The drug is administered in the form of keratinized pills so that the specific action of the drug may play its rôle in the intestines. The fæces in the normal state and under the influence of a mixed diet are alkaline or neutral, but they become acid under the influence of a considerable gastric acidity, which the secretions of the intestinal glands, of the liver and of the pancreas are unable to offset. It is in such cases that the peroxide of magnesium has given the best results. The writers then relate the histories of several cases which corroborate the opinion of Robin that there is in this drug an antiseptic as well as antidiarrhœic power, most important, when the origin of this diarrhœa is fermentation. It is only when the contents of the intestine are acid that the magnesium peroxide decomposes and sets free its oxygen.—*Bulletin Général de Thérapeutique*, June 15, 1904.

The American Journal of the Medical Sciences, June, 1904.

Mental Symptoms Associated with Pernicious Anæmia.—William Pickett states that a composite picture of the mental disturbance in these cases presents a shallow confusion with impairment of the ideas of time and place (disorientation), more marked on awakening from sleep. The patient fabricates, relating imaginary experiences of "yesterday" in a circumstantial way. Illusions, particularly of identity, are common. Hallucinations appear at times, pertaining to any of the senses. Based upon these, persecutory delusions arise which are usually transient. They may persist for considerable periods and be thus somewhat fixed. They may be even systematized. This psychosis is mainly an abeyance of mind. It rarely presents the spontaneous excitement by which some types of confusion seem to merge into true mania. The term amentia seems appropriate for it. Korsakoff's disease and folie Brightique resemble it closely.

The Relation of Cells with Eosinophile Granulation to Bacterial Infection.—Eugene L. Opie concludes that certain bacteria (bacillus tuberculosis, bacillus choleræ suis), producing somewhat chronic, fatal infection in guinea-pigs, cause the eosinophile leucocytes gradually to disappear from the circulating blood. The study of dead tissues gives little indication of the behavior of the eosinophile leucocytes during the course of bacterial infections. After the inoculation of an organism producing an infection from which the animal is capable of recovering, eosinophile leucocytes disappear from the peripheral circulation, to a proportion of less than 1%. The number then increases for a few days, after which it again becomes normal. When bacteria are introduced into the peritoneal cavity of the guinea-pig, the large mononuclear and eosinophile cells contained in the peritoneal fluid, form compact clumps, which adhere in great part to the surface of the omentum, so that for a time eosinophile cells have almost completely disappeared from this fluid. After about an hour they again appear. Eosinophile cells, rarely if ever, act as phagocytes, ingesting bacteria. Eosinophile leucocytes are ingested by large mononuclear cells (macrophages). In cases of severe bacterial infection, eosinophile myelocytes accumulate in the spleen and may be found in the circulating blood, within from two to four hours after inoculation, showing that these elements are derived from the bone-marrow and are not found in the spleen. Bacteria exert a chemotactic influence upon cells with eosinophile granulation, attracting them from the bone-marrow into the blood, and from the circulating blood to the site of inoculation.

Traumatic Intestinal Rupture, with Special Reference to Indirect Applied Force.—Emanuel J. Senn calls attention to internal injuries with no manifest external lesions. These injuries are most frequent in men and young adults, on account of their greater exposure to injury. Generally speaking, blows above the level of the umbilicus are unlikely to cause intestinal injuries. Pathologically the injuries may be classified as (1) contusions; (2) rupture: incomplete, complete. Contusions may be of all degrees. Incomplete ruptures, when one or two of the tunics are torn, in all probability are frequent; however, according to pathological investigation, they are considered rare. Complete ruptures, when all the tunics are ruptured, are more often brought to view on the operating table and in the post-mortem room. They are usually single, but may be multiple. As intestinal rupture is usually the consequence of a severe trauma in the neighborhood of the sympathetic centers, the classical symptoms of shock generally develop. Retroperitoneal emphysema signifies injuries to the duodenum or colon. Fecal matter is less apt to escape than gas, but the latter may escape in very small quantities. Vomiting is considered of great diagnostic importance by many. As to prognosis, Siegel gives the following statistics: In cases operated upon in the first 4 hours, the mortality is 15.2 per cent.; in the first 5 to 8 hours, the mortality is 44.4 per cent.; in the first 9 to 12 hours, the mortality is 63.6 per cent.; in those operated upon later, the mortality is 70 per cent. The writer states that in all cases of abdominal contusions the prognosis should be guarded, and the patients ought to be kept under careful observation. When there is the least suspicion of rupture, immediate laparotomy should be performed. The writer advises the incision made through the linea alba below the umbilicus, as giving a better survey of the abdomen. The bowel should be examined methodically from a fixed point till the lesion is found. When for some reason operation cannot be performed, and an expectant course is followed in simple contusion or in cases of ruptured intestine, the patient should be placed at rest with an ice-bag on the abdomen. Nourishment should be given only by rectal enemata. Opium is indicated to diminish peristaltic action of the bowels.

The Envelope of the Red Corpuscle and Its Role in Hæmolysis and Agglutination.—S. Peskind gives the following résumé: Various facts of an historical, chemical, and physical character show that the red blood corpuscles possess an envelope. From the action of hydroxylamine hydrochlorate, it appears most probable that the envelope is not a differentiated membrane, but a part of the stroma which is condensed to form the surface layer of the corpuscle. The envelope is hæmoglobin-free and consists of nucleoproteid cholesterin, lecithin, and mineral constituents. It is elastic, smooth, and apparently possesses a certain glaze which presents the agglutination of normal corpuscles with each other and makes them less accessible to the action of toxins. Agglutination of blood corpuscles is due to an effect on the envelope produced by various biological products and chemical reagents whereby the envelope is made sticky. Agglutinins probably lower the resistance of the blood corpuscles torward toxins and other agents. From the fact that in nature they almost always occur in company with a hæmolysin, it is suggested that the agglutinins bear some coöperative relation to the hæmolysins similar to that existing between the intermediary body and the complement. The "resistance" of blood corpuscles depends in large part upon the condition of the envelope. Toxins of disease cause the envelope to deteriorate, either partly or completely. "Vacuolization of the hæmoglobin" can be explained satisfactorily on the assumption of a minute lesion in the envelope, which allows the surrounding fluid to enter and thus permit, of a localized laking at this point. The function of the envelope is, in part, to make possible various metabolic processes, principal among which is the complex process known as internal respiration. Another important use is to protect the corpuscles from deleterious substances. But the very chemical constitution of the the envelope may at times serve for the undoing of the corpuscles.

Health of the Russian Army.—An official report from Manchuria states that up to June 26 the officers and men in hospital reached a total of 7.136 per cent. and 3.943 per cent. respectively of the whole force. After the rains began the percentage of officers in the hospitals increased to 8.383 and of the men to 4.646. The proportion of infectious cases rose from 2.19 to 8.52, including 1.99 per cent. of dysentery.

Book Reviews.

Materia Medica, Pharmacology, and Therapeutics. Inorganic Substances. By Charles D. F. Phillips, M.D., LL.D. (Abdn. and Edin.), F.R.S. and F.R.C.S. (Edin.). Hon. Fellow Medico-Chirurgical College, Pennsylvania; Member of the Academy of Medicine of America; Examiner in Materia Medica, University of Aberdeen, Late Examiner in the Universities of Edinburgh and Glasgow; Member of the Physiological Society of London; Late Lecturer on Materia Medica and Therapeutics at the Westminster Medical School. Third Edition. London, New York, and Bombay: Longmans, Green & Co., 1904.

This is a book of exceptionally practical value, full of useful suggestions, and one that cannot fail to be of service to the physician in his fight with disease. The greater part of each section is devoted to the indications for the therapeutic employment of the drug under consideration, though sufficient space is accorded to a discussion of physiological action and to the preparations and dosage of the remedies. The author speaks out of his own experience in the treatment of disease, and this gives to the book the charm and value of the personal touch associated with the clinical lecturer; but at the same time he does not ignore the discoveries of others in the same field.

The chief fault with the book is the lack of system in its arrangement. Under the heading of "water," for example, sun baths and air baths, the Finsen light, and electric baths are treated of, and as there is only a therapeutic index and none of remedies the matter is practically inaccessible. An index of remedies would have obviated this objection; one was in the former edition, and we cannot but think the author has made a mistake in omitting it from this edition.

Le Malattie dei Paesi Caldi, Loro Profilassi ed Igiene, con un' appendice; La vita nel Brasile. Regolamenti di Sanità pubblica contro le infezioni esotiche. Pel Dottor Carlo Muzia. Con 154 incisioni e 11 tavole. Milano: Ulrico Hoepli, 1904.

The author of this volume is a surgeon in the Italian Navy. The subject is treated under seven heads: General diseases, local diseases, diseases and lesions produced by animals and animal parasites, intoxications, cosmopolitan diseases occurring in the tropics, insolations, and hygiene of the tropics. The work is copiously indexed, and contains a bibliography of the principal works on the subject. While the size of the work precludes any monographic presentation, the terseness of expression enables the author to present much in the space at his disposal. The illustrations relate chiefly to the microorganisms of the various diseases, and corresponding to the disproportionately large number of parasitic diseases the illustrations of the animal parasites are numerous. Maps are also given showing the geographical distribution of several of the more important diseases.

Physiology and Pathology of the Urine. With Methods for Its Examination. By J. Dixon Mann, M.D., F.R.C.P., Physician to the Salford Royal Hospital; Professor of Forensic Medicine in the Victoria University of Manchester. With Illustrations. London: Charles Griffin & Co., Ltd.; Philadelphia: J. B. Lippincott Company, 1904.

And still they come! Another book on the urine! "Wer reitet so spat durch Nacht und Wind?" It is an Englishman this time, but what he has given us is a genuine surprise. A book not of the type of the now so frequent "guides to the examination of urine." It differs from them in its thoroughness, completeness, and up-to-dateness.

Some of the constituents of the urine, irrespective of their chemical constitution, have been grouped together to facilitate their study; a description is furnished of the systemic conditions in which each urinary component appears in anomalous quantities; the more important pathological states, recognizable by specific alterations in the urine, are separately dwelt upon; and the results of the latest studies in metabolism, so far as affecting the urine, are given in just sufficient minuteness to be of real assistance to the investigator.

The titles of the various sections will demonstrate the practical value of the book: General Characteristics of the Urine, Inorganic Constituents, Organic Constituents, Amido and Aromatic Acids, Carbohydrates, Proteids, Nitrogenous Substances, Pigments and Chromogens, Blood-coloring Matter, Bile Pigments, Bile Acids, Adventitious Pigmentary and Other Substances, Special Characteristics of Urine, Urinary Sediments, Urinary Calculi, Urine in Its Pathological Relations.

The subjects treated upon in the section on "Special Characteristics of Urine" being particularly useful to the progressive clinician and impressing upon the book the stamp of modernity, are: Reducing Power, Oxidative Power, Proteolytic Power, Toxicity, Molecular Concentration (Kryoscopy), Conductive Capacity, and Calorimetry.

The illustrations are of the stereotype variety and mediocre; the stronghold of the otherwise superb book does not lie in its chapters on the microscopy of the urine.

Bericht über Gallensteinlaparotomien aus dem letzten Jahr; unter gleichzeitiger Berücksichtigung der nicht operirten Falle. Von Prof. Hans Kehr. Munich: J. F. Lehmann, 1904.

This contribution to the subject of gallstone surgery forms part of the annual report of Kehr's private surgical clinic in Halberstadt, Germany. During the past year he had the opportunity of examining over 300 cases of cholelithiasis and performed an operation in 137 of these. The particular points to be noted in his technique are the disinfection of the hands with soap and water and alcohol (no bichloride); the most stringent asepsis; gastric lavage before operation in almost all cases; nitrous oxide and chloroform anæsthesia; restricted numbers of nurses and assistants; the use of silk and sterile gauze, neither catgut nor iodoform gauze being employed. Although Kehr does take an extreme view as to early operation, and recognizes that a so-called latent period comes on spontaneously in about two-thirds of the cases. This is the reason why various internal methods of treatment are often followed by such favorable results; the latter are *post hoc*, not *propter hoc*. Kehr has recently traced about two-thirds of the last series of 500 cases which he operated upon for gallstones. About 90 per cent. of these remained free from colic, icterus, and hernia, and were completely cured.

The Medical News Pocket Formulary. By E. Quin Thornton, M.D., Assistant Professor of Materia Medica in the Jefferson Medical College. New (Sixth) Edition, Revised. Philadelphia: Lea Brothers & Co., 1904.

This collection of prescriptions seems to have taken well with physicians. The diseases are printed in large type and alphabetical order, so that reference is easy. There are 287 pages of small type. There is a useful table of doses, and the revision has brought the matter well up to the times.

The Medical Epitome Series of Pediatrics. A Manual for Students and Practitioners. By Henry Enos Tuley, A.B., M.D. Edited by V. C. Pederson, A.M., M.D. Philadelphia and New York: Lea Brothers & Co., 1904.

This little book is intended as a pocket guide to the beginner in medicine. It deals with the pathology, diagnosis, and treatment of the diseases common to children. After each chapter a series of questions and answers are inserted to bring out the most valuable points. It also gives many points on the differential diagnosis. The author has contributed very frequently to pediatric literature and is entitled to a hearing. The chapter on infant feeding is quite complete. In a future issue the vital points concerning the brain and nervous system should be incorporated, as well as a chapter on intubation.

Lectures on Clinical Psychiatry. By Prof. Emil Kraepelin. Authorized Translation from the German by Dr. James Johnstone. New York: Wm. Wood & Company, 1904.

This is a volume of 300 pages containing thirty clinical lecturers on the commoner varieties of insanity, such as Melancholia, Manic-depressive Insanity, Dementia Præcox, General Paresis, Epileptic Insanity, Puerperal Insanity, Insanity after acute diseases, Paranoia, the insanities of alcoholism, morphine and cocaine, Traumatic Insanity, Imbecility, Cretinism, Different Forms of Delusion, Compulsory Ideas and Irresistible Fears and Morbid Personalities. The lectures are simple, readable, and will undoubtedly be very acceptable to American physicians. During the last few years the classification of Kraepelin and the nomenclature which has grown out of the classification have taken a firm hold upon young American psychiatrists, and, although at the present time there are indications that the teachings of Wernicke are gradually gaining ascendency, still the followers of Kraepelin are many in this country. The book makes no attempt to cover the entire field of psychiatry but rather to deal with the familiar forms of alienation. Nor is there any space devoted to discussions of classification or theories of the pathogenesis of insanity. The general practitioner, especially if he is not familiar with the author's views, will find this volume of great aid in the interpretation of mental cases encountered in his practice, and the specialist will find it a valuable clinical compendium, to be used in connection with the treatise on insanity by the same author or any of the other standard works.

Society Reports.

AMERICAN GYNECOLOGICAL SOCIETY.

Twenty-ninth Annual Meeting, Held in Boston, Mass., May 24, 25, and 26, 1904.

TUESDAY, MAY 24—FIRST DAY.

THE society met in the Boston Medical Library under the presidency of Dr. Edward Reynolds of Boston.

An address of welcome was delivered by Dr. Charles M. Green of Boston, which was responded to by Dr. Henry T. Byford of Chicago.

Treatment of Gallstones Found as a Coincidence in Abdominal or Pelvic Operations.—Dr. JOHN G. CLARK of Philadelphia stated that among the unsettled questions in abdominal surgery, the treatment of gallstones found as a coincidence in abdominal or pelvic operations might be considered a debatable one. He followed the plan at present of removing gallstones which were found in the course of another operation, if the patient's condition permitted of this extra operation. Although it was stated that 95 per cent. of gallstones produced no symptoms, he believed that this statement should not be applied to cases as one met with them at the time of an operation. In his review of recent literature he had been especially impressed with the fact that knowledge of the early stages of cholelithiasis was very indefinite, and that many cases which came to operation for more or less urgent symptoms did not have the clinical symptoms of colic and jaundice, as usually taught in medical schools. In view of this hiatus in the early history of this disease, he believed that many symptoms now attributed to gastralgia, indigestion, functional disturbances of the gastrointestinal tract, etc., would, as knowledge increased, be ascribed to the presence of gallstones with associated infection, which was so frequently found in cholelithiasis.

In referring to the etiology of gallstones, he said that three facts had been prominently established: (1) That the bile was not bactericidal. (2) That the microorganisms in the gall-bladder were predisposing, if not absolute, causative factors in the formation of gallstones. (3) When gallstones were present in the gall-bladder, infection in that viscus was much more likely to take place.

He mentioned three general avenues through which infection might enter the gall-bladder. (1) From bacteria circulating in the genital blood stream and reaching the liver through the hepatic veins; (2) by the direct passage of bacteria into the common bile duct from the duodenum; (3) by the transportation of bacteria from the intestine through the portal circulation.

He then recurred to the frequently quoted statement that 95 per cent. of gallstones did not produce symptoms, and showed from his own series of cases that in at least 50 per cent. there were varying symptoms from undoubted attacks of colic and jaundice to less pronounced gastrointestinal symptoms. To justify operative intervention in cases which were not producing well-defined symptoms, the mortality and morbidity should be a very low one. In his own experience no death had occurred, nor had there been any serious complication referable to the secondary operation. In lieu of the fact that the additional operation did not seriously jeopardize the life of the patient, and also because he had seen two patients die from cholelithiasis a year or more subsequent to an abdominal operation, in which, had the routine exploration been made, the gallstones might have been easily removed, he believed that the best interests of the patient would be conserved if the gallstones were removed as a secondary part of another operation, in the event of their being found. He appended the history of twelve cases to his paper, in which the various operative points, as well as the significant facts in symptomatology, were elaborated.

Dr. R. STANSBURY SUTTON of Pittsburg said that gallstones did not always produce symptoms which demanded or justified resort to operation. If they were encountered during the course of another operation, they had better be removed.

Dr. GEORGE M. EDEBOHLS of New York had occasion at one time to operate on a woman who presented marked dyspeptic symptoms. In addition, she had movable kidney, chronic appendicitis, and induration in the region of the gall-bladder. He anchored the kidney, removed the appendix through a lumbar incision, pulled the gall-bladder into the lumbar wound, and found the stone about four or five centimeters in length, pear-shaped, and nearly filling the gall-bladder. The attending physician was positive that the gall-bladder did not produce symptoms of stone in it. He would not let him remove the stone from the gall-bladder. A year later he opened the woman's abdomen for some other condition, making an incision near the gall-bladder. He investigated the gall-bladder, found it was perfectly healthy, and that the large stone had either passed or had been dissolved. The treatment after the previous operation consisted of the use of olive oil for about a month, and whether this had anything to do with the passage of the stone, he did not know. At any rate, the stone had disappeared and had left no trace of its former existence.

Dr. A. PALMER DUDLEY of New York emphasized the importance of looking beyond the gall-bladder for trouble. He believed that stones were formed in the liver ducts themselves, and that from a stagnant circulation cholester in nuclei formed, and that only a small proportion of stones were found in the gall-bladder. He would not hesitate to go into the center of the liver. In fact, in the last case he had, in which the diagnosis of gallstones had been made by a medical *confrère*, he boldly went into the gall-bladder, but found no stone. He found the duct dilated; he went five inches into the right lobe of the liver, as far as he could reach with his finger, and packed the liver full of iodoform gauze, put an apron of gauze over it, and the patient was well to-day. He would explore the center of the liver in searching for such deposits.

Dr. BROOKS H. WELLS of New York said that in the last few years he had used practically the same measures as those outlined by the essayist. A number of patients coming under his observation had complained of obscure symptoms, of so-called functional indigestion. In them he found either disease of the gall-bladder, an over-distended gall-bladder from obstruction elsewhere, or trouble referable to gallstones.. By making a small or large incision, as seemed necessary, cleaning out the gall-bladder and draining it, the patients had obtained remarkable relief from the symptoms that were supposed to be due to functional indigestion.

Dr. SETH C. GORDON of Portland, Me., said that when the abdominal cavity was opened for other purposes, and he was quite sure the patient could stand it, he would examine the gall-bladder thoroughly, and if gallstones were found, he would remove them. He cited cases in support of this line of reasoning.

Dr. HIRAM N. VINEBERG of New York said that under the influence of the teaching of Kelly he had been in the habit of doing what had been advocated by the essayist, but after hearing a discussion on gallstones in the common duct and in the gall-bladder by one of the Mayos, he had changed his method. Simply opening the gall-bladder and removing the stones did not effect a cure, as proven by three or four cases that occurred in his own practice. If the gall-bladder was diseased, however, it should be removed.

Dr. J. M. BALDY of Philadelphia said that gallstones existed in the gall-bladder for years without causing any material discomfort, but that when infection occurred they were liable to give trouble. There was not the slightest question but what large numbers of cases of so-called stomach trouble, or chronic indigestion, sooner or later proved to be cases of gallstones or of gall-bladder disease. With reference to removing gallstones when operating for some other intraabdominal condition, the surgeon

should consider the physical condition of the patient, the surroundings, etc., and as to whether the patient was willing to undergo the additional risk of a second incision for the gall-bladder operation.

Dr. Walter P. Manton of Detroit quoted Ochsner as saying that he had tried almost everything in the so-called cases of chronic dyspepsia, without affording relief; yet after opening their gall-bladders and removing gallstones which were found, the patients were cured. Dr. Manton had seen a number of such cases, and contended that the removal of gallstones, or the gall-bladder, if diseased, was the thing to do. He did not believe there was any solvent ever invented which could dissolve gallstones.

Dr. Beverly MacMonagle of San Francisco, Cal., stated that when the abdomen was opened for some pelvic or abdominal trouble, the operator should investigate the gall-bladder. If gallstones had been making the patient ill, causing dyspepsia, or if there were adhesions around the gall-bladder, one should operate. The conditions that arose in the pancreas as a consequence of gall-bladder disease and of gallstones were serious, and if the surgeon could do something of a prophylactic nature, without adding to the risk of the patient's life, it was a wise thing to do.

Dr. Clark, in closing, said the formation of gallstones through bacteria had been clearly demonstrated by a series of experiments. He did not believe anyone would strongly advocate operation unless the gallstones were producing symptoms.

Ovarian Pregnancy.—Dr. J. Clarence Webster of Chicago reported a case of ovarian pregnancy. There was a right ovarian irregularly rounded swelling, measuring 7 by 8 cm. There was no evidence of rupture into the peritoneal cavity. The adhesions were recent. Sections of the ovarian swelling consisted mainly of extravasated blood and disseminated fragments of the chorion. No evidence of transformation of ovarian connective tissue into decidua was noted. It was certain that the pregnancy did not start in a Graafian follicle.

Dr. J. Whitridge Williams of Baltimore said there was no doubt that ovarian pregnancy occurred, but it was the rarest of all forms of extrauterine pregnancy. In regard to the Muellerian origin of ovarian pregnancy, he was not quite convinced of it. While there was no doubt that Muellerian tissue might be found in the ovary, as mentioned by the essayist and confirmed by numerous observers, he thought it was going too far to advance that view in explanation of every case of ovarian pregnancy.

Dr. John T. Thompson of Portland, Me., referred to a case of ovarian pregnancy he had reported at a previous meeting of the society. He called attention to the nature of the structures in which pregnancy occurred, and to the frequency with which rupture might occur in the early days.

Dr. Edward P. Davis of Philadelphia removed an ovarian pregnancy about a year ago, the histology of which had not been completely worked up as yet, although a diagnosis was made very early of the nature of the tumor from the enlarged ovary. The indications were that the pregnancy did not originate in the Graafian follicle.

Dr. Lapthorne Smith of Montreal had diagnosed ectopic pregnancy by the clinical symptoms; had operated, and had found hæmatoma of the ovary. He had said to his students that he was sorry that his diagnosis was wrong, because authorities maintained that there was no such thing as ovarian pregnancy, but after hearing what had been said he was convinced there was.

Ureterolithotomy.—Dr. J. Wesley Bovee of Washington, D. C., in a paper on this subject, gave the history of the operation, and then discussed the size and number of calculi. The routes for reaching and extracting ureteral calculi, he said, were the transperitoneal and the extraperitoneal. The latter might be subdivided into loin, inguinal, vaginal, rectal, sacral, perineal, and transvesical. The transperitoneal route should never be the one of election, as the danger of peritoneal infection from the urine was too great. Of the extraperitoneal routes, the selection would depend largely upon the location of the calculus or calculi, although the operation of Ceci, of removing it through the rectum, should only be considered justifiable when the stone had practically sloughed through into the rectum. In a class of cases characterized by the stone having been lodged in the intravesical portion of the duct and later sloughed into a pocket in the bladder wall, which it had made for itself, the vaginal and inguinal routes were the only safe ones, although in so stating he was not unmindful of the number of cases in which suprapubic cystotomy had been done. He discussed the removal of the calculus from the ureter, and the methods for so doing; also the treatment of the ureteral opening.

Speaking of drainage, he stated that all ureterolithotomy wounds should be drained. This was because the urine was practically never normal, therefore rendering wound infection probable. The possibility of urinary leakage subsequent to operation afforded another positive indication for drainage.

Nephrectomy for Primary Tuberculosis of the Kidney.—Dr. Hiram N. Vineberg of New York read a paper on this subject. Tuberculosis of the kidney, both primary and secondary, was more frequently met with in women than in men, in the proportion of about two to one. It was different from what occurred in men; renal tuberculosis in women was rarely associated with tuberculosis of the genital organs. A cystitis in women that resisted the topical applications of the silver nitrate solution by the Kelly method should be looked upon with marked suspicion as being of tuberculous character, even though repeated examinations of the urine should show an absence of the tubercle bacillus. The differential diagnosis of a non-tuberculous from a tuberculous cystitis with the aid of the cystoscope was not as reliable as the therapeutic test outlined in the preceding sentence. Pronounced reddening or ulceration about the mouth of one of the ureters, with absence of other bladder changes, was held by some authorities as pathognomonic of tuberculosis of the corresponding kidney; while the sign was an important one, too much weight should not be attached to it in women. In most cases the removal of the diseased kidney would bring about practically a cure of the descending cystitis. He doubted the wisdom of the advice to cure the cystitis before undertaking the removal of the kidney in women, owing to the fact that the disease was most frequently primary and unilateral, the modern tests for determining the functional capacity of the second kidney were not as essential as in men. Catheterization of the supposedly healthy kidney was a procedure to be avoided, when, as was frequently the case, there was associated a tuberculosis of the bladder. The prognosis of nephrectomy in renal tuberculosis in women was exceedingly good. Of the writer's four cases operated upon, seven, five, two, and one and one-half years ago, respectively, all were alive and in good health.

Dr. Joseph E. Janvrin of New York reported a case of a woman who had been ailing for two years with what was supposed to be a renal calculus. Before operating, Dr. Willy Meyer examined the woman, and agreed with him that the case was probably one of calculus in the pelvis of the kidney, with possibly calculi in the ureter. The kidney was removed, and it was found that the pelvis was infiltrated with tuberculous deposits in the very early stage. The patient made a good recovery and was well to-day.

Dr. J. Wesley Bovee said that if one read the proceedings of the late meeting of the German Congress, he would be impressed with the comparatively large proportion of cases in which primary tuberculosis was found in both kidneys, or the very small proportion in which one kidney alone was involved. As to the indications for operation,

on tuberculous kidney, the surgeon should be sure that the opposite kidney was capable of carrying on the function of excreting urine for the whole body before he decided to remove one tuberculous kidney. A nephrotomy might be done, and the kidney most markedly diseased drained, without taxing the other kidney to a great extent. As regards cystitis in tuberculosis of the kidney, it was a late, not an early, symptom.

Dr. Philander A. Harris of Paterson, N. J., said that in cases of tuberculosis of the kidney it was difficult, when the bladder was corrugated and changed by the pathology present, to find the ureter; but by painting the entire field of the bladder with some solution sufficiently colored with a swab, as Prussian blue, he had succeeded in finding the ureters in the case of a girl which he could not otherwise locate.

Dr. Seth C. Gordon operated on a man, removing a kidney which was situated low down in the abdomen, painful, and bound down by adhesions. The patient died eleven days after the operation, and post-mortem examination showed that the man had no other kidney. Two years afterward he removed a very large kidney from a woman, who lived twenty-eight days after operation. For twelve hours she did not have a single uræmic symptom, nor was there a drop of urine secreted, and she died in full possession of her faculties. Post-mortem examination revealed that she had no other kidney.

Dr. J. M. Baldy said it was not uncommon to have medical men in the wards of the policlinic ask if the ureters had been catheterized in the cases of supposed kidney disease, and not infrequently a perfectly healthy kidney was palpated and found on one side which utterly failed to secrete with the patient under an anæsthetic or without it. In some instances this failure on the part of the kidney to secrete was undoubtedly brought about by the influence of the anæsthetic. At any rate, anæsthesia would reduce the quantity of secretion very materially. He had had exactly that same experience a number of times in patients whose ureters he had catheterized, but to whom no anæsthetic had been given.

Dr. George M. Edebohls said that some four or five years ago he read a paper on "The Other Kidney and Contemplated Nephrectomy." In it he advocated that before removing a kidney an incision should be made on the opposite side to determine by actual inspection and palpation (1) the presence of another kidney, and (2) its probable health, so far as could be determined macroscopically, before removing the diseased kidney. In spite of the advance made in diagnosis, and its limitations in kidney diseases, he had adhered to that rule in all nephrectomies performed since that time, and in one case he had saved a woman's life by so doing.

Dr. J. Riddle Goffe of New York reported a case bearing on the removal of the ureter in connection with tuberculosis of the kidney, the patient having been operated on by him in 1896. She was a woman of twenty-two, who had a very large tuberculous abscess of the right kidney. He removed the kidney and three inches of the ureter. She made an excellent recovery, excepting that she had a sinus which lasted four months and then healed. Patient was now a graduate nurse and in perfect health.

Dr. Edward Reynolds of Boston gave his experience of ten nephrectomies for tuberculous disease, seven of them being complete nephro-ureterectomies, all successful, so far as operative mortality was concerned.

Hypertrophies and Inflammations about the Urinary Meatus.—Dr. Robert L. Dickinson of Brooklyn read a paper on this subject, saying that their frequency, and the suffering caused, gave them an importance out of all proportion to their minute size. Overlooked because hidden among folds of mucous membrane. They were explained by embryology. A tiny ribbon ran from the rear of the vaginal opening forward, on each side of the vaginal and urethral openings, across the vestibule to disappear beneath the clitoris. This fold was persistent in those cases in which the hymen ran forward of the meatus, or the meatus seemed to open on the anterior vaginal wall. This fold was enlarged by friction or traction to produce flaps or labia, hanging out each side of the meatus. They were found only with corrugated labia. Dilated or dilatable urethra often accompanied them. The urethral glands opened near the apex of the flaps. They were long, running down into the anterior column of the vagina. Swelling from infection differed from hypertrophy. The cure of chronic inflammation was only feasible by obliteration of the glands. A fine probe, passed to the bottom of the gland, rendered the vestibular-vaginal surface tense; the cautery wire cut out the probe. For piles of the meatus, the cautery wire was used after cocaine; for prolapse or dilatation of the urethra, resection of the anterior vaginal wall or paraffine injections into the urethrovaginal septum produced a sigmoid profile.

Surgery of the Female Urethra.—Dr. Ely Van de Warker of Syracuse, N. Y., read a paper on this subject. The urethra, he said, appeared like an insignificant part, its vital relations were negligible, its anatomy was relative, and acquired its importance from its related organs, but it might be said to epitomize a large share of the suffering that woman's pelvic organs inflicted upon her. The amount of disturbance caused by a simple irritation of the urethra to the bladder and indirectly to the kidneys afforded striking proof of the validity of reflected nervous disturbance.

The term sacculation was regarded as better than the old one, urethrocele. Its major cause was mechanical, as inflammation alone was not adequate to its production. The urethra might be said to belong to the perineal rather than the pelvic zone of organs. The walls of the canal depended in a measure upon the support of the perineal body. It was often associated with long-standing rupture of this part. Restoration of the perineum was therefore essential to treatment of the sacculation. When large, an elliptical flap of the walls of the urethra was removed and the edges brought together by fine silk sutures. Prolapse of the mucous lining of the urethra the author had generally associated with long-standing urinary troubles of various kinds. It was, therefore, probably due to a gradually progressive condition, and was a typical ptosis, and complied with the general law of genital prolapse. After removing the prolapsed portion there was a marked tendency to recurrence unless the conditions which gave rise to it were treated and cured. Bladder incontinence and dribbling were often lifelong conditions. That this was due to a defective action of the sphincter vesicæ was more than doubtful.

Stricture of the urethra, in the author's experience, was common in women. Any condition that tended to produce linear or annular thickening led to stricture. Specific urethritis might produce stricture, but it was not the frequent cause alleged by some writers. Stricture of large caliber might be located and measured by the Otis bulbs, but never by the sound, as was recommended by old systematic writers. Annular stricture of the meatus was the form most commonly met with. These ought to be incised and made to heal in an open condition by the frequent passage of the sound. Dilatation alone was too painful and required too much time. As to eversion of the mucous membrane at the meatus, its prototype was the fusiform stricture of Otis, and its surest cure was by dilatation.

Pyelitis Complicating Pregnancy.—Dr. Edwin B. Cragin of New York read this paper (see page 81).

A Second Case of Puerperal Eclampsia Successfully Treated by Renal Decapsulation.—Dr. George M. Edebohls of New York said the first case, reported to the society a year ago, illustrated the immediate cure by renal decapsulation of puerperal convulsions, recurring with great and increasing violence after the birth of the child, a period at which the hitherto final resource of forced

delivery was, of course, no longer available. In presenting the case the opinion was advanced that resort to renal decapsulation in the undelivered woman suffering from puerperal eclampsia might obviate the necessity of forced delivery. The case now reported illustrated the correctness of that opinion. Renal decapsulation was performed upon a woman pregnant near term, suffering from puerperal eclampsia, and almost complete suppression of urine. The convulsions were arrested, the flow of urine was reestablished, and a threatened death from uræmia was averted. Two days after all this had been accomplished, labor began spontaneously, and living twins were born. One child died soon after birth. The second child and the mother were in perfect health four and a half months after the termination of pregnancy. Renal decapsulation thus became the rival of forced delivery in cases of puerperal convulsions of renal origin in the undelivered woman. In puerperal convulsions, occurring or recurring after delivery, it constituted the final resort when all other measures had failed.

Wednesday, May 25—Second Day.

Primary Repair of Lacerations of the Cervix Uteri.—Dr. Edward P. Davis of Philadelphia read the first paper in the symposium on this subject. Experience in fifty-three cases had led to the following conclusions: When the patient was not infected and when the tissues had not been subjected to sufficient violence to threaten necrosis and laceration of the cervix, one-half inch or more in extent was present, primary closure had been followed in his experience with good results. These cases usually occurred in primiparæ in whom resistance in the soft part occasioned sufficient delay and fatigue to require delivery by forceps. They were also seen in cases of premature labor, whether spontaneous or induced, in which the cervix was not physiologically softened for perfect dilatation. They were also found in patients having spontaneous labor with very strong expulsive efforts, and with large children. Naturally those cases in which the mechanism of labor was abnormal through posterior rotation of the occiput, face presentation or breech presentation, predisposed to laceration of the cervix. While primary closure of laceration of the cervix was indicated in the conditions just described, certain conditions were necessary for its successful performance. These conditions were outlined. Dr. Davis then described the technique of the operation, and the after-treatment. The number of cases under observation was 53. In these, good union occurred in 45, fair union in 6, no union in 7, while infection developed in none. In 84.9 per cent. the operation was successful; in 11.3 per cent. it was moderately successful, and in 3.8 per cent. the operation failed. The percentage of infection was *nil*. He pointed out the objections which were commonly urged against this operation, after which he said that in appropriate cases in his experience immediate closure of the cervix had given no inconvenience to the mother, and had been followed by excellent results. The operation was not advised for those who do not practise obstetrics with good surgical technique, and who were not competent to operate on the genital tract.

Cervix Suture on the Fifth Day after Delivery.—Dr. Robert L. Dickinson of Brooklyn said that no complicated or considerable perineal injury should be repaired at the close of labor, but three to five days later. This had an important bearing on lacerations of the cervix, as this was the ideal time to restore such injuries. The huge œdema, the bruising, and the uncouth distortion of the vaginal portion just after delivery rendered identification of the parts that should be brought together impossible, and attempt to coapt accurately, guess work. Therefore, whenever possible, the cervix should be sewed on the fifth day. The frozen sections of the puerperal weeks showed that then, and not till then, shrinkage had occurred. Bleeding no longer obscured the difference between flayed surface and torn structure. Then only were the surroundings of the operation, in the way of illumination, table, time, and a rested personnel possible. This applied particularly to private practice. The conditions under which the cervix should be repaired at the close of labor were: (1) Bleeding from a firmly contracted uterus, notwithstanding ergot, heat, holding, and tampon. Here there was a spurting artery. (2) When the cervix injuries were clean cuts, of known location, as after Duhrssen incisions. (3) When, in the immediate repair of a moderate perineal injury, a tear of the cervix is found. The conditions under which the cervix should be repaired several days after labor were: Exhaustion of patient, or surroundings and conditions which precluded careful work. (2) Extensive injuries, except when these persistently bled or had been cut by the surgeon. (3) When accompanied by complicated or considerable injuries to the pelvic floor. The author drew attention further to the alterations produced by granulation and contraction in these wounds when left alone, so that the scarred, swollen, averted, or cystic cervix months or years after injury gave uncertain indications for accurate restoration to the original condition.

General Considerations of Laceration of the Cervix Uteri.—Dr. J. M. Baldy of Philadelphia stated that as a matter of clinical fact, let the cervix uteri be torn deeply and if the parts were preserved from infection, the greater part of the tear would heal spontaneously, and the rest of it would remain perfectly healthy, as much so as would the lobe of the ear which had been torn through by the weight and drag of our great-grandmother's earrings. The lips would remain uninfiltrated, of normal size and thickness, with no eversions and no erosion of the lining mucous membrane. In such a case there would be no untoward symptoms and no bad effects whatever. There was a tendency amongst obstetricians to repair these lacerations primarily. The objections to such practice were manifold, and he admitted a prejudice against it. These objections were pointed out. Whatever might be ideal surgery under the exigencies of actual practice, the treatment for recent lacerations of the cervix remained, and he believed would remain, rigid local cleanliness, excepting where there was sufficient hemorrhage to demand a ligature. Where non-infection could be insured, and where the torn lips were not unnecessarily disturbed, by the careless use of the nozzle of a syringe, spontaneous healing of these lacerations might be expected to a greater or lesser degree, and what tear remained, when nature was through with her work, would be of a healthy character, would give no future trouble, and would need no surgical interference. The symptoms of chronic lacerations of the cervix uteri were essentially local in their production and remained so in their manifestations. He had no sympathy with the views which attributed reflex symptoms to these lesions. In uncomplicated cases, in which there existed simply a laceration of the cervix uteri, with everted and eroded lips, producing a constant leucorrhœa and a feeling of weight and uneasiness in the pelvis and about the rectum, these so-called reflex symptoms did not exist. There was one belief prevalent which would warrant, nay demand, a repair of every lacerated cervix—the belief that lacerations of the cervix produced carcinoma. In this belief he took no part, and no one had, to his knowledge, as yet produced a single scientific fact which would uphold such a theory. In twenty years' work he had not seen a single case of cancer develop in a laceration of the cervix which he had refused to repair.

Intrapelvic Hæmatoma.—Dr. J. Whitridge Williams of Baltimore reported a case of intrapelvic hæmatoma following labor, and made some remarks on the treatment of incomplete rupture of the uterus.

President's Address.—Dr. Edward Reynolds of Boston in his presidential address, said, among other things, that the society owed its preëminence along its chosen line less to the words than to the prolonged and daily labor of the eminent men who had composed it in the past, and must owe its future to the lifework of the equally able men who were to fill its membership in the coming years. He said the use of the printed abstract published beforehand had of late become increasingly prominent in many societies, and in the British Medical Association this use of the abstract had reached its highest terms. It was seldom wise to adopt wholesale the regulations of other organizations. It was usually better to let changes follow a more gradual and natural evolution under the needs of the individual assembly, but the methods of the English association were worth a passing consideration. A Fellow of the British Medical Association who desired to present a paper at one of its meetings, must put it in the hands of the secretary complete and in the form in which he desired its publication a number of weeks before the meeting, and the communication might be of any length he chose. A paid secretary, a qualified and experienced medical author, then abstracted each paper in the form and length which he considered best fitted for its public delivery. This official then read the abstracts to the society as they were called from the program. Such a reading inaugurated each discussion, and the member whose ideas had been thus succinctly set forth before his associates took part in the discussion and closed it. The ideas of individual members by this method were better and more intelligently presented to the society than if they had read their complete papers. In this way the time of the society was economized, full debate was encouraged, and the members had the advantage of publishing to the world papers in which their points were set forth at the fullest length and without time limitation. Dr. Reynolds said that such a method was perhaps too far advanced for our present needs or possibilities, yet it had many advantages, and it seemed to him worth calling attention to as one toward which the society might well advance.

Would it not be wise to give this method, or a modification of it, a year's trial? In conclusion he expressed his thanks for the kindly personal feeling which had actuated the Fellows when they elected him president, for which, and for the many personal pleasures which he had enjoyed in the society, he was, and would always gladly remain, their willing debtor.

The Preventive Treatment of Pelvic Floor Lacerations.—Dr. J. Clifton Edgar of New York read this first paper in a symposium on injuries to the perineum. The most important part of the management of the second stage of labor was the prevention of pelvic floor lacerations, lacerations of the fourchette in primiparæ, and superficial tears about the vulvar orifice in both primipara and multipara often occurred, were often unavoidable, and usually readily healed with simple asepsis. Deep lacerations were avoidable in normal, ordinary cases of labor. The factors which tended directly or indirectly to produce pelvic floor lacerations were numerous, but for convenience he arranged these in three major classes. These were concisely stated as (1) too rapid expulsion of the fœtus, so that tearing instead of stretching resulted. (2) Relative disproportion in size between the presenting part and the parturient outlet. (3) A faulty mechanism of labor, whereby the larger circumference of the head and shoulders than necessary passed through the parturient outlet.

From an extended clinical experience, he could speak most enthusiastically of the preliminary digital stretching of the vulvar outlet in primipara, and especially in elderly primipara, as a prophylactic measure in perineal protection. Regarding shoulder delivery, the author firmly believed that the posterior shoulder was responsible for many instances of deep pelvic-floor laceration. Furthermore, moderate ruptures caused by the passage of the head were often increased and rendered serious by the subsequent passage of the posterior shoulder. He had been most successful with the following method of shoulder delivery, and either the lateral or dorsal posture of the patient could be used at will. This method was not new: (1) The delivery of the shoulders was delayed, if possible, until nearly complete rotation of the bisacromial diameter had taken place. (2) The fetal head was taken in the hand and gently raised or pushed, so as to bring the anterior shoulder well up behind the symphysis, thus giving the cervico-acromial diameter of the fœtus at the outlet instead of the bisacromial. (3) The posterior shoulder was now allowed to pass out spontaneously and whenever possible manual extraction should be avoided, as this increased the risk of perineal rupture. (4) During the detention of the anterior shoulder behind the symphysis, the fetal hand of the opposite arm lying across the fetal chest would usually soon appear in the vulva. He had found that delivery might be safely assisted by slowly flexing this forearm and arm out through the vulva and thus delivering the posterior shoulder by slight traction on the posterior arm. (5) Should the foregoing be impracticable and delay in the expulsion of the posterior shoulder occur, he had found gentle traction upon the head, the fingers encircling the neck, to be preferable to traction with a finger in the axilla. (6) Should there be delay in the delivery of the anterior shoulder, after expulsion of the posterior, it was best remedied by making traction directly downward, with the hands placed on the sides of the head, taking care not to make too great pressure on the perineum. As a last resort, traction might be made by a finger in the axilla.

Placing Sutures before the Lacerations Occur.—Dr. Lapthorne Smith of Montreal spoke of the importance of closing up even small tears of the perineum, so as not to leave raw surfaces for septic absorption. It was important to close large tears so as to retain the function of the pelvic muscles. The best time to put in these stitches was just before the head pressed on the perineum, while the patient was anæsthetized, and before the parts had lost their relative positions. With the left finger in the vagina and the thumb in the rectum, a large perineum needle on a handle was passed just under the vagina, threaded with silkworm gut; the two or three stitches hung loosely in a Pean forceps until the placenta had been delivered, when they were quickly tied, bringing the parts exactly together as they were before the tear.

Immediate Repair of Injuries of the Pelvic Floor.—Dr. Henry C. Coe of New York said that he had selected this topic in order to emphasize the fact that by careful attention to puerperal lesions at the time of their occurrence the patient could be spared much future trouble. He assumed that it was the usual practice of modern accoucheurs to repair injuries to the pelvic floor at once, but it was one thing to suture visible tears and another to repair deeper lesions. Even when perfect union of the lacerations was obtained, the occurrence of prolapsus, cystocele, and rectocele months afterward proved that there had been some fault in the technique. The fact of the separation of the fascia and levatores ani muscles must be recognized as well as the superficial tear, especially after difficult instrumental deliveries. An illustrative case from the writer's practice was cited. The tendency of the accoucheur after a tedious instrumental case, in which both physician and patient were exhausted, was to spend as little time as possible in repairing lesions of the soft parts, trusting to aseptic technique to insure perfect healing. The writer was firmly of the opinion that it paid to do the work thoroughly at the time, unless the patient's condition was such as to render delay advisable. He had had such good results from immediate operations that the intermediate did not appeal to him. In conclusion, he alluded to the fact that the modern accoucheu

must be a surgeon as well as an obstetrician. It was expected of him to leave the patient in as good condition as he found her, otherwise he properly laid himself open to criticism.

Uniformity in Pelvic and Cranial Measurements.—Dr. A. F. A. King of Washington, D. C., read a paper on this subject in which he reached the following conclusions: "(1) That at present the measurements of the normal pelvis and fetal head are indefinite and unsettled, and must continue so to be so long as they are determined by our present methods of mensuration. (2) The chief purpose in obtaining the normal dimensions of these structures being for teaching and learning the normal mechanism of labor, it is proposed to adopt an ideal or hypothetical head and pelvis, upon the dimensions of which all authorities may agree. (3) In the adoption of such ideal structures, it is unnecessary and undesirable to define any measurement with exact precision—no fraction smaller than one-fourth of an inch, or than half a centimeter (in the metric system) being required. (4) Race variation forms no real obstacle to the proposed plan, and other apparent difficulties can be overcome. Finally, should the proposition meet with approval, it is suggested that this society take the initiative in bringing the matter in proper form before some forthcoming international medical congress for general adoption."

Accordingly, a committee was appointed by the president to consider the matter of uniformity in pelvic and cranial measurements, and report at the next annual meeting.

Non-operative Local Treatment in Gynecology.—Dr. Willis E. Ford of Utica, N. Y., in reading the first paper in the symposium on this subject, said that no one would deny that greater good had come from surgical treatment of diseases peculiar to women than was ever dreamed of by the early gynecologists who did not operate. No comparison of results could be made. He did not think it was true, however, that the specialty ought to become purely surgical. Pathology learned by pelvic and abdominal surgery ought to be clearer and better than was ever discovered post-mortem. It was fair to assume that men who did this work had a better idea of the natural history, progress, and dangers of these diseases than those who did not operate; and that, therefore, the early treatment ought to be in the hands of men who were also doing surgical work. The nervous habit could not be cured by surgical procedure. What was commonly called neurasthenia was not a disease, but an established habit, possible only to those who had from birth an unstable or weak nervous constitution. Before the mental symptoms began was the time to prevent neurasthenics from becoming permanent invalids. That the nervous habit could not be cured by surgery had been proven by the fact that the removal of diseased ovaries, and such like operations on epileptic women, had not cured the epilepsy or neurasthenia. The argument, therefore, was that in those ailments that tended to disturb the emotions, especially those of the reproductive organs of men or women, the the serious thing was not the pain experienced, but the permanent invalidism which was brought about by the protracted local sensations that in time disturbed the mental equilibrium and brought about the invalid habit. These local irritations ought to be treated by skilled gynecologists, and not allowed to develop either the mental or physical ailments which were so common a result. These arguments were enough to make the profession to revive its interests in non-operative procedures. Recent displacements, especially in young people, and acute infections were mentioned as demanding non-surgical care early, if one wished to avoid the more serious ailments, and especially the most serious of all, the mental disorder called neurasthenia.

Dr. Walter P. Manton of Detroit, Mich., said that the ignorance of proper methods, together with the fascinations of operative measures, had brought the local treatment of pelvic disease into disrepute. Three of the factors, which among others at the present time were largely responsible for the neglect of medical gynecology, were: (1) The average physician's lack of knowledge in the accurate diagnosis and local treatment of pelvic disease. (2) The allurements and fascinations of surgery, and (3) competition in the field of practice. While it was true that no amount of instruction could impart a *tactus eruditus*, still anyone could acquire a knowledge of the primary principles underlying the correct interpretation of gynecic ailments, if opportunity was offered for the practical examination of patients under competent direction. In ignoring the benefits to be derived from medicine, he was convinced that surgery had gone too far and that it had overshot the mark, but that the present tendency to operative measures in all conditions affecting the pelvic organs could not be ascribed so much to the good which surgery, rightly directed, was capable of accomplishing as to other elements which had entered into the case was also evident. In the best of hands the results from local treatment in pelvic diseases were frequently slow in manifesting themselves, and discouragements were often met with, but in suitable cases persistent effort would ultimately attain the desired end. The objects of local treatment were the relief of pain and irritation, often of a reflex nature; the allaying of congestion and inflammation; the absorption of the products of inflammation, and the reposition of displaced organs. In the regulation of the uterine functions, in congestions and mild inflammations of that organ and surrounding parts, and in displacements of the uterus, with and without adhesions, the application of proper local treatment was of signal value; while in prolapse of the tubes and ovaries, even in the presence of extensive adhesions, but without ascertainable morbid changes in the organs themselves, vaginal tamponade offered the simplest and most efficient means of reposition and cure.

Treatment Preparatory to Operation.—Dr. Henry C. Coe of New York introduced his remarks with the statement that while his early training had led him to believe that such treatment was practically indispensable in cases of so-called "cellulitis," subsequent experience had convinced him that this notion was not in accordance with pathology or common sense. He had expressed skepticism on this subject as long ago as 1886, when he read a paper on the "Exaggerated Importance of Minor Pelvic Inflammation," and subsequent experience had only served to confirm his opinion that old pelvic exudates and adhesions were not *per se* a contraindication to operations on the uterus. Modern aseptic technique was a sufficient safeguard against danger from this source. The reader contrasted the old practice of keeping a patient in a hospital for several months, with the preparatory treatment between each minor operation, with the present plan of performing a combined operation at one seance and sending the patient out in three or four weeks. He questioned the actual value of the hot vaginal douche, local applications to the vaginal fornix, etc., previous to trachelorrhaphy. At the same time, he admitted the remarkable results often observed as regards the absorption of extensive pelvic exudates. Acute and subacute inflammations in and around the adnexa formed the real contraindication to operation, and doubtless surgeons were not always as careful as those of the former more conservative generation in selecting their cases. Competition and the rush of modern life were responsible for some ill-advised operations, minor as well as major. In regard to major operations, the author thought that (excluding pus cases) general preparatory treatment of the patient was rather more important than local. He believed, however, that the admirable results obtained by the pioneers in the treatment of vesicovaginal fistulæ were due to careful

preparatory treatment, such as the division of cicatrices, stretching of the vagina, etc. Fortunately we were seldom called upon to handle such complicated cases as those described by Sims, Emmet, and Bozeman. With all our improvements in technique, we had not yet outgrown all the wisdom of our old teachers.

Postoperative Local Treatment.—Dr. J. Riddle Goffe of New York said the experience of all observers was that local treatment relieved congestion, pain and discomfort; inaugurated, hastened, and accomplished the absorption of œdema, plastic exudate, adhesions, and pseudo-hypertrophy.. If it would relieve these conditions, how much more certainly would it prevent them? It had been found serviceable in preventing the deposit of plastic exudate and the reformation of adhesions in cases in which these were present at the time of operation. It was especially valuable in cases subjected to vaginal section for the relief of sterility. The author reported several instructive cases to substantiate the points made in his paper.

The Implantation of the Human Ovum in the Uterus.—Dr. Charles Sedgwick Minot of Boston discussed this subject by request. He stated that the human ovum produced upon its exterior during its earliest stages of development a thick layer of cells, the trophoblast. The function of the trophoblast was to corrode away a portion of the mucous membrane of the uterus, making a cavity in which the ovum lodged itself. The trophoblast thereupon underwent a hypertrophic degeneration, such as to produce a series of irregular spaces, which persisted and became the intervillous spaces of the placenta. Papillary outgrowths of the chorionic mesoderm meanwhile penetrated the trophoblast, initiating the formation of the chorionic villi. The trophoblastic cells over each mesodermic outgrowth persisted in two layers, the inner cellular, and the outer syncytial. These two layers represented the first stage of the villus ectoderm. Similar observations had been made upon primates, and were compared with those upon the human subject. He compared briefly the method of implantation in man with that in other animals, to show that the trophoblast was of general occurrence, and that by destroying uterine tissues it inaugurated the formation of the true chorionic placenta.

Bathing During the Menstrual Period.—Dr. J. Clifton Edgar of New York said that in the consideration of this subject several questions suggested themselves, namely, first, the advisability of bathing of any description during the menstrual period, and if at all, to what extent. Second, the use of the bath in dysmenorrhœa. Third, the use of Nauheim or other chemical baths or hydriatic procedures. Fourth, the risk of infection of the endometrium in intramenstrual tub-bathing. Fifth, the influence of modern athletics on women, lessening the risk, if any, of intramenstrual bathing. These questions were submitted to the members of the society, from whom he had received one hundred and twenty-two acknowledgments. From the replies received, and the literature on the subject, he drew the following conclusions: "(1) All forms of bathing during the menstrual period are largely a matter of habit, and usually can be acquired by cautious and gentle progression, but not for every woman does this hold good, and surf bathing, where the body surface remains chilled for some time, should always be excepted. (2) A daily tepid sponge bath (85° to 92° F.) during the menstrual period is not only a harmless proceeding, but is demanded by the rules of hygiene. (3) In the majority of, if not all, women, tepid (85° to 92° F.) sponge-bathing after the establishment of the menstrual flow, namely, second or third day, is a perfectly safe practice. (4) Furthermore, in most women the habit of using the tepid shower or tub bath after the first day or two of the flow can with safety be acquired."

The Streptococcus in Gynecological Surgery.—Dr. Hunter Robb of Cleveland, Ohio, stated that in order to arrive at some definite conclusions with reference to the streptococcus pyogenes as a cause of death in his work, he had made an analysis of all his cases in which this organism had been found during the past six years. It was shown from observations that quite a large number of his patients died, and several were unimproved. It was also noticed that in the great majority of cases in which this organism was met with, there was a previous history of infection following labor, or an induced criminal abortion. In the past six years he had had 137 cases of abortion (including a few cases of labor), in which it was necessary to carry out some form of treatment. Of this number, 104, or 75.9 per cent., recovered; 17, or 12.4 per cent., were improved; 1, or .8 per cent., was unimproved. and 15, or 10.9 per cent., died. In 16 of the 137 cases the streptococcus was found, The total number of all his cases in which the streptoccocus was found was 40, consequently those in which this organism was found following an abortion or labor formed 40 per cent. of the total number of streptococcus cases from every source. Of these, 16 patients (streptococcus cases), following abortion or labor, 4, or 25 per cent., recovered; 3, or 18.75 per cent., were improved; 9, or 56.25 per cent., died. In the whole, 40 cases from every source, in which the streptococcus was found, the results were as follows: Recovered, 20, or 50 per cent.; improved, 6, or 15 per cent.; deaths, 14, or 35 per cent. The streptococcus was found in the following combinations, given in order of frequency: (1) Streptococcus alone; (2) streptococcus and staphylococcus pyogenes aureus; (3) streptococcus, staphylococcus aureus, and bacillus coli communis. In all these cases, except three, in which they were obtained from the vagina, the organisms were obtained from the uterus, the adnexa, the cul-de-sac, or from several of these situations. In other words, they were proved to be present in places which were admittedly not their normal habitat. In the past five years he had had 724 abdominal sections, with a total number of 32 deaths, or 4.43 per cent. In 7, or 21.9 per cent., of them the streptococcus pyogenes was demonstrated. In all there were 19 cases of abdominal operations in which the streptococcus was found. Of this number, 12 recovered, or 63.2 per cent.; and 7 died, a mortality of 36.8 per cent.

Indications for Operation for Fibroid Tumors of the Uterus.—Dr. Charles P. Noble of Philadelphia presented a table of the degenerations and complications in a series of 1,188 cases of fibroid tumors operated upon by Martin, Noble, Cullingworth, Frederick, Scharlieb, and in a series reported by Hunner and MacDonald. Especial attention was called to the relative frequency of adenocarcinoma of the uterus as compared with epithelioma of the cervix. The deduction drawn from this fact was that fibroid tumors were a direct predisposing cause of cancer of the cervix. A careful consideration of the facts presented in the table, said the author, should convince anyone with an open mind that the classical teachings concerning fibroid tumors were erroneous. This teaching was that fibroid tumors of the uterus were benign growths, which usually produced but few symptoms, and which after the menopause underwent retrogressive changes, becoming smaller or disappearing; that the chief danger of fibroid tumors consisted in the fact that at times they caused hemorrhage from the uterus, and that rarely they caused trouble, because of their size or because of pressure on adjacent viscera. An analysis of the 1,188 cases showed that because of the degenerations in the tumors, about 16 per cent. of the women would have died without operation; about 18 per cent. would have died from the complications present. In addition, it was well-known that a certain percentage would have died from intercurrent diseases brought about by the chronic anæmia present in many of these cases, and by injurious pressure from the tumors upon the alimentary canal and urinary organs. In brief, at least one-third of the women having fibroid tumors, as shown by the author's table, would have died had they not been submitted to operation.

The Treatment of Gonorrhœa.—Dr. Henry T. Byford of Chicago said there was dissatisfaction with prevalent methods of treating this disease. The desideratum was a local remedy that would rapidly destroy or remove the germs without injuring the protective epithelium, and a method of application that could be used by the patient which would not carry the germs to a deeper portion of the genitourinary tract. He advocated prolonged irrigations with hot water as a basis, and spoke of frequent injections of hot water as a substitute for prolonged irrigations. He detailed his experience with urethritis in the male, and referred to hydrogen dioxide and unirritating germicidal solutions as substitutes for plain water injections, and gave their application to gonorrhœa in the female. The advantages of this treatment, when used early, were summarized by him as follows: "(1) It prevents the spread of the disease to adjacent parts. (2) It does not injure the epithelial covering, and tends to limit the infection to the superficial areas. (3) It removes more germs and pus cells than either astringents or disinfectants can destroy. It acts in the same way as constant irrigation, both in aborting and arresting the progress of the infection. (4) It can be used more frequently than astringents or strong germicides, so that the parts can practically be kept free from pus and germs all of the time, while the method of using germicides or astringents three or four times daily allows the germs and pus to accumulate and spread between injections. (5) In the male, and possibly in the female, peroxide injections may be substituted when the time and facilities for the hot water treatment cannot be had. When the discharge has become scanty and the injections cannot readily be used so frequently, a non-irritating solution of a silver salt can follow each hot water or peroxide treatment. (6) It may be used in connection with other injections for the dissolving of germs and culture material not eliminated by the douches. (7) It does no harm. It can be combined with the internal or local medication when it becomes impossible to carry it out with the necessary time-consuming detail It exemplifies the superiority of asepsis to antisepsis."

Dr. Philander A. Harris of Paterson, N. J., exhibited and described a new uterine obstetrical dilator.

Officers.—The following officers were elected: *President*, Dr. E. C. Dudley, Chicago, Ill.; *Vice-Presidents*, Drs. Henry D. Fry, Washington, D. C., and Henry C. Coe, New York; *Secretary*, Dr. J. Riddle Goffe, New York; *Treasurer*, Dr. J. M. Baldy, Philadelphia.

Niagara Falls, N. Y., was selected as the place for holding the next annual meeting, in May, 1905.

Treatment of Tabes.—O. Ziemssen discusses his method of handling this disease, which he bases on the assumption that the cord lesions are due to a disturbance in the capillary system, and that when the latter is righted the diseased tissues are regenerated. It is necessary to distinguish between the less prominent elementary disease and the secondary effects, which are a source of greater annoyance. Different remedies may be directed against one of these factors without in any way influencing the other. Ziemssen first places the patient on a thorough mercurial treatment, and unless this is carried out diligently the result is always failure. The method to be preferred is by inunctions. In addition to this the amount of fluids is restricted, as in other circulatory diseases, and special measures are directed against the secondary manifestations, such as the ataxia, incontinence, neuralgia, etc. Even where the tabes has closely followed upon a trauma, the author has used the inunctions and later found that the patients had had syphilis. It is essential in every instance to begin treatment as early as possible, for as a rule the disease has existed for some time before the patient presents himself for examination.—*Wiener klinisch-therapeutische Wochenschrift.*

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending July 9, 1904:

	Cases.	Deaths.
Measles	261	15
Diphtheria and croup	297	29
Scarlet fever	95	13
Smallpox	1	...
Varicella	29	...
Tuberculosis	359	136
Typhoid fever	39	9
Cerebrospinal meningitis	...	34

An Unusual Form of Influenza.—J Latkowski reports a localized epidemic disease characterized by a sudden invasion, chills and fever, swelling of the eyelids, muscular pains, and general prostration. Examination of the secretion from the conjunctiva showed the presence of the influenza bacillus. This swelling of the lids is an unusual phenomenon, and the author believes that the connective tissue forms the portal of *entrée* for the germs, from which they are distributed through the body.—*Wiener klinisch-therapeutische Wochenschrift.*

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended July 9, 1904:

NOTES ON SOME UNCOMMON FORMS OF NERVOUS DISEASES.*

BY L. PIERCE CLARK, M.D.,
NEW YORK.

VISITING NEUROLOGIST TO THE RANDALL'S ISLAND HOSPITAL AND SCHOOLS; CONSULTING NEUROLOGIST TO THE MANHATTAN STATE HOSPITAL, NEW YORK.

I DESIRE to place on record the following short abstracts of some uncommon forms of nervous disease in patients that have presented themselves at the Vanderbilt Clinic during the past two years. I am much indebted to Dr. Starr for his kind permission to publish the cases:

Multiple Neuritis with Intact Reflexes.—CASE I—J. S., five years old, whose case is incorporated in this report by kindness of Dr. Hart, is an imbecile and possibly epileptic. He was born at term with instruments after a prolonged dry labor of eighteen hours. He was much asphyxiated, but no convulsions were reported. There were scrofulous suppurating glands of the neck at six months. He only began to talk at three years of age. July, 1902, he suffered from what the family supposed was gastritis, but which was probably lead colic; he recovered entirely, and was well for two weeks, until September 15, 1902, when it was noticed one morning that he was lame in both feet and there was bilateral foot-drop. Two months after his hands became affected in the same manner, showing the characteristic wrist-drop of lead palsy. He handled lead during the two weeks after recovery from the illness in the summer and again in September. The relatives believe his taking strong medicine during the summer had something to do with it, but this seems improbable from the history of treatment. At present he is in the recovery stage of multiple neuritis, apparently of lead origin. All reflexes are exaggerated; no sensory changes. Great diminution of faradic and galvanic current, but no qualitative change.

In multiple neuritis the reflex action in the muscles is almost invariably lost (Gowers , but in rare cases, such as those reported by Dejerine, it may persist. Its retention, however, is exceptional, and probably depends on the escape of at least some of the fibers on which the action depends. The retention of the knee-jerk throughout the entire course of the disease cannot be explained on the basis that they are sometimes excessive in the early stages of the disease (in consequence of an irritable state of the nerves on which they depend) similar to that which gives rise to hyperæsthesia. On the the other hand, usually in the slightest grades of neuritis the reflexes are lost, however muscle tenderness is almost invariably present, indicating an involvement of the afferent sensory nerves.

Myoclonus.—CASE II—B. S., eleven years old, Jewish. Two years ago, without rheumatism, heart disease, or fright or other known causes, a lightning-like clonic spasm developed in the left biceps, triceps, pectoralis major, latissimus dorsi and sternomastoid, and in a few weeks the same muscle of the right arm also became involved. The spasm was then as now nearly bilateral, lightning-like, and clonic in character, occurring twenty to forty times a minute. There were good and bad days, but there was never more than a few minutes of entire freedom from the spasm. In a few months the muscles of the pelvic girdle became involved, particularly the glutei, quadriceps, the adductors, and the sartoriis. He had no difficulty in swallowing; there was, however, a diaphragmatic grunt. He cannot inhibit the morbid movements now as long as formerly. Of late the supinators of the forearms and peroneal group in the legs have been occasionally involved. No spasm in fingers or toes have ever been observed, although of late infrequent facial spasms have occurred. The muscles involved first in the disease are now involved most. Musculature is good; no atrophy; no sensory changes; all reflexes are normal. There is marked disturbance in writing. He inhibits the spasms while writing single words, and then in the frequent pauses the "jerks" are intense. The worst sample given here was on one of the patient's "bad days," when the uninhibited spasms were so sudden and brisk as to make "rockets" before the hand could be voluntarily withdrawn from the paper in the act of writing.

The illustrations on the following page are copies of the handwriting in this case of myoclonus: (For similar specimens see the report of the author's cases in the *Archives of Neurology and Psychopathology*, Vol. 2, Nos. 3–4, 1899.)

Cases of myoclonus, although not rare, are still uncommon. In diagnosticating the affection we permit a wider latitude in the disease complex than formerly. Although the essentials of the affection are usually held to embrace the symptom of bilateral clonic lightning-like muscular spasm involving proximal muscles most or exclusively, cases are undoubtedly reported in which one or more of these so-called essentials are very much modified or absent. It is interesting to note in France, where the tics have been most thoroughly studied, that the names of "multiple tics" and "electric chorea" (Henoch-Bergeron's disease) still do service for many obviously well-marked cases of myoclonus. Even in this country myokymic (Schultze) as well as multiple tics and electric chorea are frequent designations for myoclonus. In Russia also Koschewniskow's epilepsy can hardly be other than myoclonus-epilepsy. Bechterew also reports from time to time altogether too many cases of choreic epilepsy. The latter is an extremely rare association in the experience of most neurologists. We believe, as Oppenheim holds, that these peculiar tics and choreas should be arranged under the head of myoclonus. It will then be possible for us properly to classify the different types of the affection. An ambitious attempt in this direction has already been undertaken by Dana in the *Journal of Nervous and Mental Diseases*, June, 1903.

*Read before the Academy of Medicine, Section on General Medicine, May 17, 1904.

Paradoxical Pseudohypertrophy in Infantile Cerebral Hemiplegia.—Case III—C. W., male, ten years old, family history of epilepsy, insanity and alcoholism, rheumatism and tuberculosis. Personal history always good. Smallpox at five, and while in the convalescent stage he had a relapse, septicæmia set in and multiple abscesses formed. After a prolonged convalescence from the relapse infantile cerebral hemiplegia developed. The convulsions were, however, general and continued for many

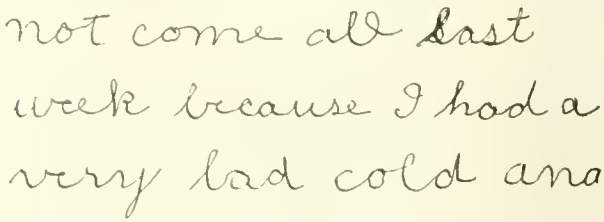

Fig. 1. Patient had been under the influence of sedative treatment (bromide and chloral) for a week when this specimen was written. No loss of control is shown, except in a slight degree in the word "last."

hours. The next day after the convulsions a left hemiplegia was noticed. The convalescence from this lesion was prolonged, and three months after the initial stroke he had status hemiplegicus unilateralis (left) attended by high fever. There were forty-seven grand mal fits in four hours; they all occurred with an order of muscular march, beginning in the left hand, the side paralyzed, as is usual in such cases. He has now grand mal, petit mal, and psychic attacks of epilepsy every two or three months two, three, and five times daily. The

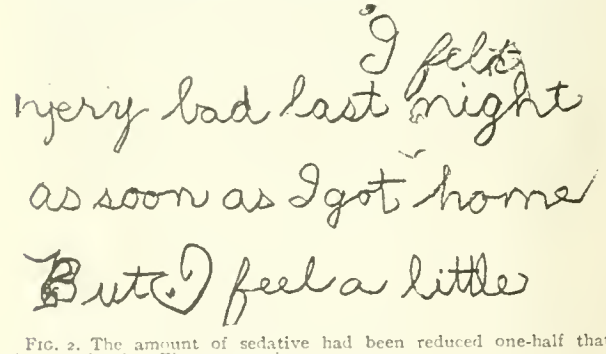

Fig. 2. The amount of sedative had been reduced one-half that given at the time Fig. 1 was written.

hypertrophy of the left calf on the paralyzed side was first noticed three years ago. The remainder of the left side, however, remains moderately atrophic, true to the usual type or law of infantile cerebral palsy cases. The fits are always followed by a more or less marked exhaustive paralysis in the side most participating in the spasm; the hypertrophy of the left calf is probably not true fiber hypertrophy, as the muscle action of the left leg is not so strong as the right. The boy is right-handed. The amount of hypertrophy is a half inch. The ankle is also

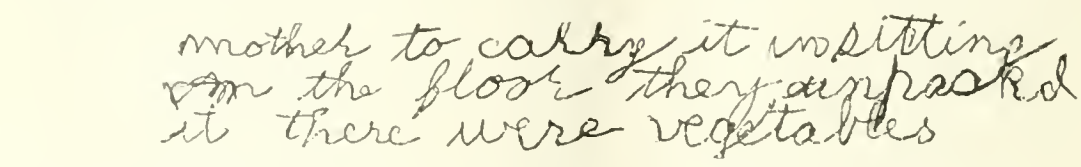

Fig. 3. The amount of sedative was reduced to one-fourth that given at the time of Fig. 1

a half inch longer on the paralyzed side, indicating hypertrophy also. The relative measurements of the extremities are here appended:

Length of arm from acrom. to ext. condyle.	Right, 9¼;	left, 9½
Circumference of arm at biceps	" 7¾;	" 7½
" " thigh at gluteal fold	" 14¾;	" 14¾
" " just above knee	" 10¾;	" 10½
" " calf	" 10;	" 10½
" " ankle	" 5¾;	" 6

Thirteen cases in all have been reported of this peculiar pathological condition in infantile cerebral hemiplegia.* An explanation for the condition is not yet at hand. Morbid agitation of the hypertrophic parts cannot be the cause, as in this case as well as in several others no athetosis has ever been present. Probably the slight nature of the cortical affection (all the other cases have been epileptic) and the slight spasticity in the involved parts may account for the hypertrophy. We, however, still await an exact pathological description of the nature and character of the lesion present in any single case.

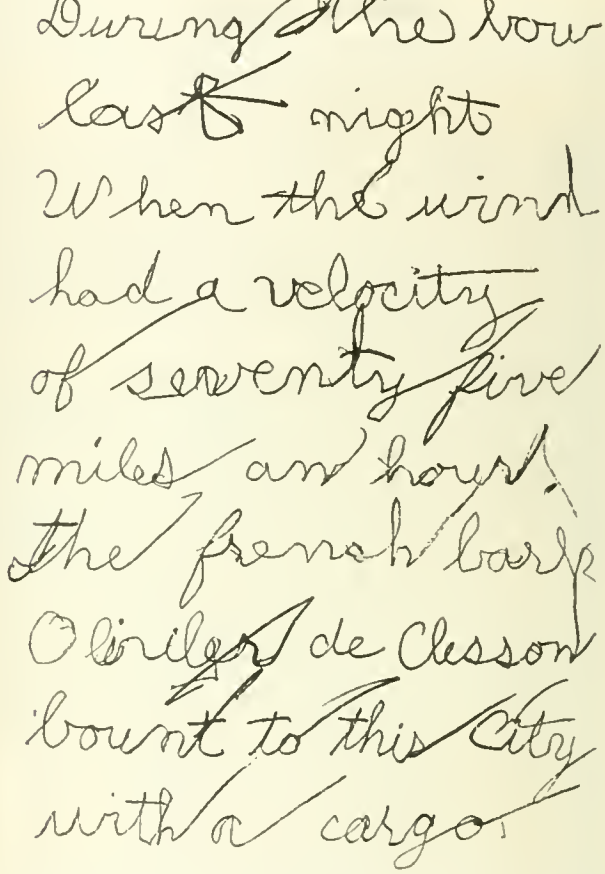

Fig. 4. In addition to the entire withdrawal of sedatives, the specimen was taken on one of the "bad days." Myoclonic interruptions are frequent and severe. The letters are all quite well formed. The muscles of the arm and shoulder cause the myoclonic movements. The handwriting is similar to that seen when one's arm or shoulder is struck violently in the act of writing.

The *x*-ray photographs (Fig. 5) show an easy clinical method of demonstrating volumetric hypertrophy in bone, muscle, and fat in parts which undergo true or false hypertrophy. It obviates the necessity of excising tissue which is a painful, and inexact means of determining these alterations although the latter method must be resorted to in order to determine whether the muscular increase is due to hyperplasia or fiber hypertrophy. I am indebted to Dr. Holden for the excellent *x*-ray negative presented.

Facial Hemiatrophy.—Case IV—The patient is married and has two children; occupation that of clerk. As a boy of five or six he reports having received a severe burn on the right side of the face, which, however left no scar, and this mishap was so slight that its occurrence was not mentioned by the patient in the early examinations. Eighteen years ago, at the age of forty-four, the

*Clark, *Journal of Nervous and Mental Diseases*, October 1, 1902, and *Archives of Neurology and Psychopathology*, Vol. 2, Nos. 3–4, 1899.

patient noticed a slight muscular contraction in the right angle of the jaw similar to that which is now present in the whole of the masseter and temporal muscles. Rubbing diminished the spasm for a time; the pain was not great, the patient felt discomfort principally, to which he soon accustomed himself. In three or four years he noticed the twitching or fibrillations as marked as now is present; now the tremor ceases at times but quickly returns on fatigue, exposure to cold, excitement, and any undue emotional stress. About six years ago he noticed a marked wasting in the right side of the face; three years ago the wasting became

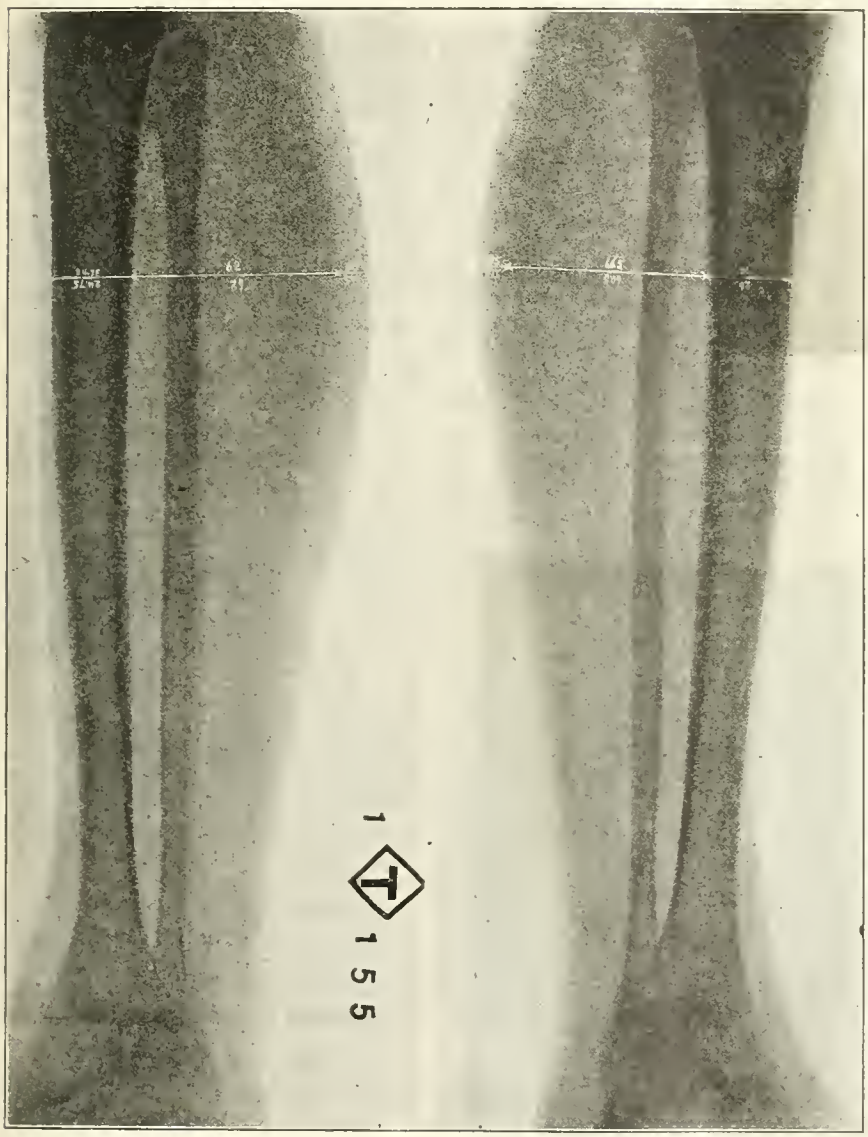

Fig. 5. Showing a method of differentiating true from false muscular hypertrophy.

so marked as to cause comment by all; the teeth decayed, loosened from the jaw, and were easily removed by a dentist. The pain became so severe last January (right trigeminal neuralgia in all three distributions of the nerve) that he sought relief at Dr. Starr's nerve clinic. The physical examination showed that all the cranial nerves were free with the exception of the fifth; the sensory portion appeared intact, except differential smell and taste were a little slow on the right side, possibly due to the functional defect expressed in the neuralgia. The atrophy of the skin, subcutaneous fat, and bone were sharply confined to our supposed skin distribution of the fifth nerve (see Figs. 6 and 7). There was no defect in the palate or tongue. It was thought that the relative atrophy of the skin, fat, and bone could be shown by the *x*-ray.

As mentioned before, there is no atrophy nor reaction of degeneration in the motor portion of the fifth nerve, the fibrillation being the only evidence of the involvement of the masseters and temporal. There is, however, shortening in the masseter muscles which apparently restrict the separation of the jaws for more than one inch; this limitation is decreased in the absence of fibrillation, and on good days he can separate them a little further than this, particularly in the morning after a full night's rest. There is no lateral movement of the lower jaw, the pterygoids apparently do not functionate.

The amount of asymmetry in this case is, of course, not so great as in those cases occurring in earlier life when a hindrance of growth increases the effects of wasting. The atrophy has always been general, not especially marked in any one spot, as in the facial hemiatrophies of sclerodermal origin or morphœal type. The hair and beard do not participate in the affection, although there is a rather marked thinning and whitening at the free border of the hair on the right side of the forehead. The lesion would seem to be one that affects all divisions of the fifth nerve, which is not entirely confined to the right side.

This case of facial hemiatrophy is shown as a probable bilateral involvement of the facial nerve in the lesion. The fibrillation present in the masseter and temporal of the right side, and to a slight extent in the left side, also proves the motor root is also involved. The fibrillary tremor is quite analogous to that seen in progressive muscular atrophy, but, since muscular wasting and weakness are but little or not at all present, and in the absence of reaction of degeneration, the apparent analogy fails in anthological comparison. I am indebted to Dr. McEntee for the history of the case and the privilege of reporting the same in this clinical study.

It is difficult to understand how exophthalmic goiter has anything to do with facial hemiatrophy, as some writers contend, but migraine or migrainous pains, hemicranial in type, may be more or less directly associated, inasmuch as many of the hemiatrophic patients have complained of neuralgic pains sooner or later, in the course of the disease, as it is an affection of the fifth nerve (sensory). Our patient has had several periods of true trigeminal neuralgia; it is doubtful, however, that true migraine with classic eye and gastric symptoms have ever occurred. Gowers believes that the condition is due to an organic disease of the fifth nerve,

with whi h we also concur. This view based upon the nature and distribution of the atrophy is further substantiated by the pathological investigation of Mendel, upon a case of Virchow's, in which Mendel

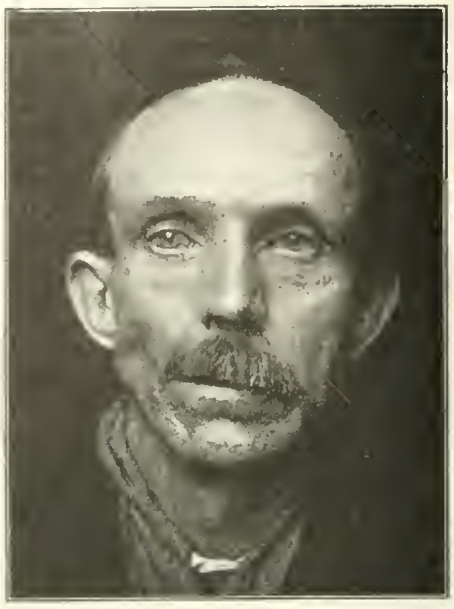

Fig. 6. Facial hemiatrophy, Case IV. Compare Fig. 7.

found interstitial neuritis in all parts of the nerve with degeneration and atrophy of many fibers in the upper root and of the cells of the locus cæruleus. It is necessary to call attention, however, to the fact, that Virchow's case was probably one of scleroderma which happened to have a hemi-facial distribution in connection with the shoulder and arm involvement. In point of fact, while the atrophy seen in morphœa or scleroderma and in facial hemiatrophy may coincide clinically, as in Schwann's case, it is by no means proven that the lesions in the two affections are identical. Moreover, fa ial hemiatrophy is probably due to a particular form of disease of the fifth nerve, as lesions of the latter are infrequently followed by hemiatrophy.

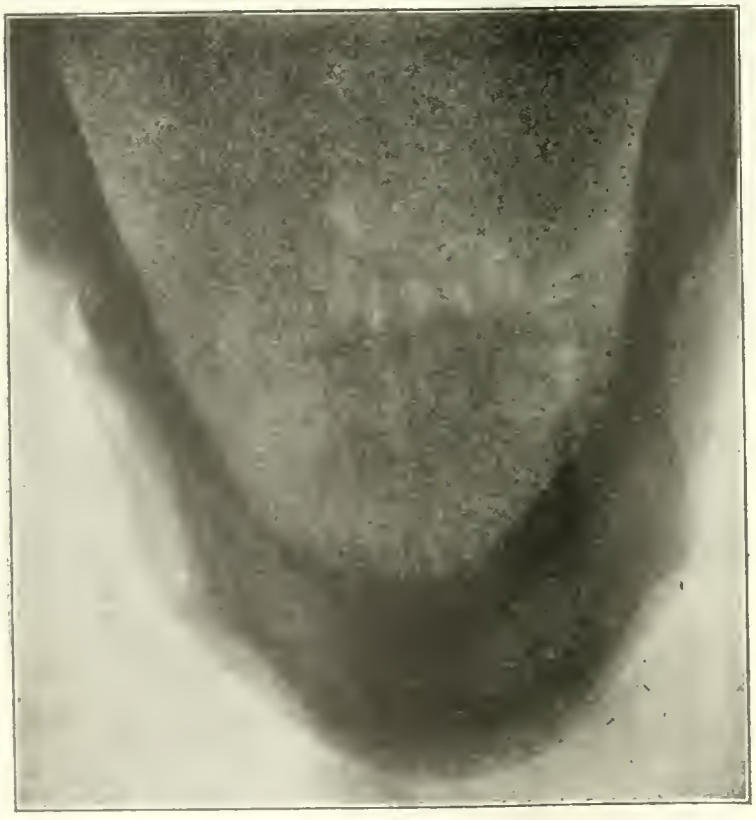

Fig. 7. Showing on the right side contour of soft parts conforming more to the bony prominences, giving an angular outline, atrophy of subcutaneous fat; marked atrophy of muscles; right ramus and angle of mandible smaller; osteoporosis of right superior maxilla; transverse distance from the shadow of the vomer to that of the outer bony wall of the nostril is diminished as compared with the left side. Compare fig. 6.

The etiology of the affection must be less patent than a trauma, which, when present (in only about one-half of all cases), has been singularly insufficient to cause so manifest a nutritional disturbance. The nutrition of all parts, except that of the muscles, appears to depend upon the posterior root fibers, to which the fifth nerve belongs for the most part. Slight trauma, therefore, might give rise to slow wasting in a chronic lesion, as in tabes, in contradistinction to a more acute affection produced by irritation. Intact sensibility does not militate against a lesion of the fifth nerve (posterior sensory root nerve), as wasting may occur in other parts of the body under analogous conditions. While, of course, the presence of trophic disturbance does not afford proof of trophic nerves, yet as Gowers suggests the rapid conduction of sensory impulses upward may be compatible with a slower conveyance of a trophic influence downward, even in the same fibers, as the latter may be lost while the former is unchanged. The lesion of facial hemiatrophy is probably of the fifth nerve, but is not of that serious nature to impair its conductibility. Cases are on record (Wolff, Muratow, Sachs, and our own) in which disorders of motility are present in tonic and clonic spasm and muscular fibrillation, showing the motor part of the fifth nerve has also been involved, and as the twitching is the initial symptom, it argues primarily for a nuclear affection. In one case a tumor beside the pons was found. Facial hemiatrophy has been produced in animals by section of the fifth nerve in the skull. We would, therefore, infer, from the variety of lesions found, that the range of possible distribution of the lesion may be quite extensive and, in point of possibility, in any part of the fifth nerve, even to its extreme cord origin, sensory or motor, or both. Finally, it must be said it may not have a demonstrable pathology, but depend upon certain nutritional changes in the nucleus or nerve fibers not discoverable by microscopical aid.

Myasthenia Gravis.—Case V—Hattie S., aged twenty-one; clerk; unmarried. There is a family history of insanity, hysteria, and tuberculosis; the cause is unknown. The patient's face "has always had a peculiar look." She had infantile rickets and has always been rather anæmic. At six years of age she had an hysterical attack, and at thirteen years of age, a true epileptic fit, tongue biting, involuntary passage of urine, frothing at the mouth, etc. Syphilis and alcoholism, congenital or acquired, appeared to play no rôle in causation. The myasthenia came on gradually. Six months before its appearance, patient had frequent typical attacks of angiospasm (digiti momortui). These attacks still persist and occur most frequently on exposure to cold, fright, and after great fatigue; they always appear in the bad days or periods. Motor weakness first appeared in the left leg; five

years ago the leg gave away after a slight amount of walking and she fell down. In six months the right leg also became equally affected. For the past year both arms (left most) have also been affected. The symptoms probably first appeared in the face, but did not seriously incapacitate the patient, it was not complained of at first. Bilateral ptosis is marked, being most on the left side and most prominent in the evening. At times diplopia has been present for a short time. There has been an alteration of the relative position of the two images at different times. There is persistent irregular nystagmoid movements, similar to those seen in conditions of general asthenia. The movements are lateral and brought out on extreme position of conjugate lateral deviation of the eyes, most marked to the left. Patient complains that words become easily blurred and indistinct while reading on bad days. Difficulty in mastication and deglutition have not been very marked. The facial expression is quite characteristic, and reminds one of a mild type of Landouzy-Déjerine form of myopathy. There is marked inability to wrinkle the forehead, raise the eyebrows, or to frown. The sphincters of the orbit are so weak that the patient is unable to keep the eyes closed against much resistance. A very poor attempt is made to show the teeth. The patient cannot pout the lips well nor empty a spoon with the upper lip, whistle or blow out a candle. Bilateral slight atrophy of tongue is to be noted.

Blood examination in this case made by Dr. Prout, is as follows:

Red blood cells	6,016,000
White blood cells	10,500

Differential count of 500 leucocytes showed:

Lymphocytes	26.8 per cent.
Large mononuclear	11.8 per cent.
Multinuclear neutrophiles	60.2 per cent.
Eosinophiles	1.0 per cent.
Mast cells	.2 per cent
	100.0

There is nothing unusual in this blood examination—in fact, it is quite normal. The high red blood cells might be noted.

Although Erb differentiated myasthenia gravis twenty-five years ago, but 114 cases have been recorded since, which shows it is still to be regarded a very rare affection. The nature of the disease appears to be fairly well outlined as a clinical entity from the symptoms: (1) myasthenic reaction (Jolly, 1895), consisting in rapid exhaustibility of the muscles by faradism, (2) rapid exhaustion of muscle by voluntary effort, (3) a state of more or less persistent paresis in the face and the extremities, (4) remarkable variability in intensity of symptoms forming "good and bad periods" and (5) facial expression, ptosis, partly obliterated facial folds, "sleepy look," etc.

Its etiopathology is still uncertain and unsatisfactory, although there is a record of fifty fatal cases, and an autopsy has been performed in thirty-one cases. The autopsies, as far as the nervous system was concerned, were negative in seventeen. Weigert and Hun have shown that a sarcomatous hyperplasia of the thymus gland was present in their cases which was not inflammatory but malignant in character; the muscles showed infiltrating foci of lymphoid cells which resembled round mononuclear cells of the thymus gland. The changes in the thymus was similar to the hyperplasia associated with status lymphaticus, but lymphoid metastases do not occur in the latter condition. Hun believes that the muscle paresis is one due to a substance which lies in the liquor sanguinis or lymph, and which constantly bathes and surrounds the muscle fibers, and in this manner brings about nutritional disease of the motor end plates.

62 West Fifty-eighth Street.

THE MODERN TUBERCULOSIS DISPENSARY.*

By S. A. KNOPF, M.D.,
NEW YORK.

ASSOCIATE DIRECTOR OF THE CLINIC FOR PULMONARY DISEASES OF THE HEALTH DEPARTMENT; VISITING PHYSICIAN TO THE RIVERSIDE SANATORIUM FOR CONSUMPTIVES OF THE CITY OF NEW YORK; CONSULTING PHYSICIAN TO SANATORIUM GABRIELS, GABRIELS, N. Y.; THE CONSUMPTION HOSPITAL OF WEST MOUNTAIN, SCRANTON, PA., ETC.

Among the multiple means of fighting tuberculosis as a disease of the masses, in large and even in smaller cities, there the tuberculosis dispensary stands out preëminently. What this relatively new institution is requires some explanation. It is a dispensary created, built, equipped, and managed for the exclusive treatment of indigent persons afflicted with pulmonary or laryngeal tuberculosis. The modern conception of the treatment and management of ambulatory tuberculous cases demands the creation of such institutions. Those of us who began our medical career fifteen or twenty years ago will remember the almost universal indifference of our teachers as well as ourselves when in our dispensary practice we came across a tuberculous case. The sooner we could dispose of it, the better we thought we did our duty. Some cough mixture and some cod liver oil was the routine treatment. There was no time, nor did we think it necessary, to teach the patient to take any precaution with his infectious sputum, or to give him any other hygienic instructions. The value of breathing exercises in such cases was thought of by but few.

How different is it to-day! To avoid as far as practicable the contact of the tuberculous patient with other patients, separate classes are created in many of our general dispensaries; but the ideal, of course, must always be the entirely separate and especially constructed tuberculosis dispensary.

The institution I have the honor to be connected with is, to the best of my knowledge, the first municipal tuberculosis dispensary especially built for that purpose in the United States. For obvious reasons it is not called a dispensary, but has for its official name "Clinic for Pulmonary Communicable Diseases of the Health Department of the City of New York." While neither my distinguished chief, Prof. Hermann M. Biggs, nor my colleague, Dr. John S. Billings, Jr., nor myself, consider the building ideal, there are many features connected with its construction which may serve, in a measure, as a model for the establishment of similar institutions. The building is centrally located, adjoining the Health Department's building, on Fifty-fifth Street and Sixth Avenue. It is a one-story structure, and is composed of a registration room, a drug room, a waiting room for women, a waiting room for men, two dressing rooms for patients, two examination rooms, an *x*-ray room, a laryngological room, one small dressing room for nurses and one for doctors, also toilet facilities for patients and employees. There are tiled floors throughout the building, all corners are rounded off, all rooms are light and well ventilated. A special treatment room for the operation of the pneumatic cabinet is in course of construction, and I hope an appropriation for the establishment of a little hydrotherapeutic installation will soon be forthcoming. All the furniture, as

*Opening address for the Symposium on Tuberculosis Dispensaries, delivered before the Section on Medicine of the New York Academy of Medicine, May 17, 1904.

desks, tables, benches, chairs, stools, closets in the drugroom, etc., are made of white enameled iron, easily cleaned and disinfected. The desks and tables are covered with plate glass.

The nurses wear the regulation white dress, and to each physician in attendance the Health Department furnishes three suits of white washable material, which these gentlemen wear during their work. Everything is done to reduce the danger from infection and reinfection. When during auscultation it is desirable to have the patient cough, Fränkel's mouth-mask is made use of to avoid drop infection. For the benefit of those who may not be familiar with this useful appliance, I beg leave to describe it briefly and illustrate it by the accompanying drawing. Fränkel's mouth-mask is composed of a metal ring, large enough and bent to fit the external contour of the mouth, a supporter, saddle and rings —the latter for the attachment of a band to pass around the patient's head to hold the mask in place. A fresh piece of gauze is placed between the supporter and the saddle every time the instrument is used. It goes without saying that those who have gone to the trouble to examine the deposits on these pieces of gauze, have not infrequently found the tubercle bacilli and other pathogenic microorganisms.

To show the aims and objects of our clinic, permit me to quote briefly from the circular of information issued by the Board of Health previous to the opening of the institution:

1. *The Early Recognition and Accurate Diagnosis of Cases of Pulmonary Tuberculosis.*—It is now generally admitted that tuberculosis is a curable disease, and that incipient tuberculosis, under favorable conditions, tends to recovery. But to insure such recovery, the diagnosis must be made at the earliest possible moment. Not only will careful physical examination of the patients be made, together with repeated sputum examinations, as required, but also in some cases *x*-ray examinations will furnish assistance in arriving at an early and correct diagnosis.

2. *The Care of Patients Applying for Treatment.*—This will include not only medical treatment, but also the furnishing of circulars of information in various languages (English, German, Yiddish, Italian, Chinese, Ruthenian, Polish, Hungarian, and Russian), careful instructions as to the nature of the disease, and the necessary personal and hygienic precautions to be taken to prevent the infection of others. Paper sputum cups will be supplied to indigent and needy cases, and also proper food (milk and eggs).

3. *The Continued Observation at Their Homes of Indigent Needy and Ambulatory Cases, Including All Those Discharged from the Public Institutions of the City.*—A special staff of trained nurses will visit the patients at their homes to see that the instructions given will be observed, that the sanitary surroundings are satisfactory, and that such assistance as is required is afforded. Suitable cases will be referred to the various charitable organizations for food fuel, ice, etc. Special attention will be paid to the children in the family and every effort made to prevent their infection.

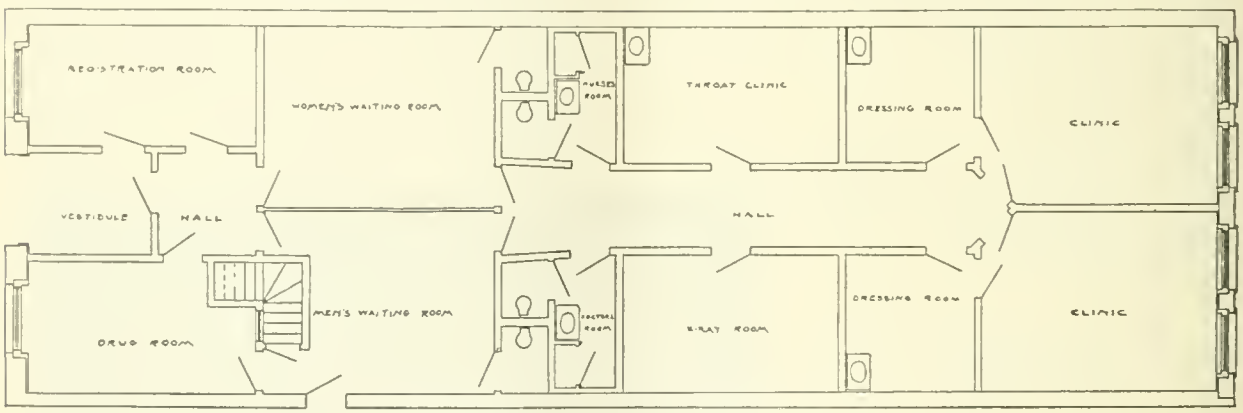
4. *The Removal to a Hospital of Cases Requiring Such Care.*—These fall under three heads: (*a*) advanced or bedridden cases, with profuse expectoration, who will not or cannot take the necessary precautions against spreading the disease, and whose presence at home is a menace to others in a family; (*b*) cases able to get about who are unable to work and entirely dependent upon their earnings for their livelihood; (*c*) incipient cases, who stand a fair chance of recovery if removed to sanatoria outside of the city.

5. *The Provision of a Municipal Institution to Which All Cases of Tuberculosis May Be Referred.*—(*a*) By physicians (charity patients, etc.); (*b*) on their discharge from hospitals or sanatoria; (*c*) by the various charitable organizations throughout the city; (*d*) by persons doing individual charitable work who come in contact with such cases.

6. Extension and strengthening of the sanitary control of tuberculosis among the poor by the Department of Health.

7. *Care of Laryngeal Cases.*—The involvement of the larynx is one of the saddest complications of pulmonary tuberculosis, and the pain, distress, and discomfort of the patients are exceedingly great. While the prognosis in these cases is extremely grave, yet under proper treatment recovery takes place in some instances, and in every case the distress of the patient can be relieved and be made more comfortable. A special throat clinic has been fitted up, and special attention will be paid to such cases.

To illustrate the general management of such a dispensary, will you permit me to give you here the rules and regulations for the physicians, nurses, and employees of our clinic, which were worked out by my colleague Dr. Billings and myself, and were approved of by Dr. Darlington, Commissioner of Health, and Dr. Hermann M. Biggs, the Medical Director:



DEPARTMENT OF HEALTH CITY OF NEW YORK

CLINIC FOR TREATMENT OF COMMUNICABLE PULMONARY DISEASES.

The clinic is open every day, except Sundays and legal holidays, from 9 A.M. to 4 P.M.

The morning classes are from 10 to 12; the afternoon classes from 2 to 4 o'clock.

On Monday, Wednesday, and Friday evenings the clinic is open from 8 to 9 o'clock.

The attending physicians are expected to arrive punctually and enter their names in the book kept for that purpose in the office.

In case any physician is prevented from attending to his class, he will notify one of the associate directors (Dr. Billings or Dr. Knopf) and arrange with one of the other physicians to substitute for the time of his absence.

The general history of new patients coming to the dispensary having been taken by the nurse in charge of the registration room, the history card is carried by the attending nurse to the physician.

A jar for the collection of sample sputum for bacteriological examination is then given to the patient, and he is assigned a seat in the waiting room.

The examining physician may dictate to the attending nurse the results of his physical examination. It is, however, desirable that the signs indicating chest deformation, dulness, flatness, râles, etc., be marked by the examining physician himself on the diagrams printed for that purpose on the examination card. (This should be done with red ink).

Each patient is to be given a leaflet of instruction,

especially designed for the Clinic with such additional advice by the physician as the case indicates.

Prescriptions are to be made out in duplicate (carbon paper), dated and signed by the physician, and the nature of the prescription recorded on the history blank in every instance.

If it be desirable that the patient should be kept under the supervision of a nurse at home, should enter a hospital, or should receive charitable aid, this fact should be stated on the history card.

On the second and later visits of the patients to the clinic, all notes are to be made on a "later" history blank.

The nurses will report at the clinic promptly at 9 A.M. and will remain until 4 P.M., or later if necessary. One hour is allowed for lunch, but at least one nurse must always be in the dispensary between 9 A.M. and 4 P.M.

In case of absence on account of illness or other causes, nurses will follow the usual departmental rules as to written notification of absence, request for leave of absence, and physician's certificate.

The service of the nurses is divided into registration and attending nurses, but their duties are interchangeable.

All complaints, requests for supplies, etc., should be made to the nurse-in-charge.

The duty of the registration nurses is to receive the patients in the registration room, and there, even before taking their names, they should instruct the patients in the primary rules for the prevention of tuberculosis and other infectious respiratory diseases.

The patient is given a sputum cup and gauze, which he must use in case he has to expectorate.

When coughing without expectoration, the patient must hold the gauze provided in front of his mouth to prevent drop infection and to prevent him from taking his often much soiled handkerchief out of his pocket while in the clinic.

After impressing upon the patient the importance of these regulations and insisting upon their being carried out faithfully, if the patient has no admission card, the name and the residence are asked. The name is then looked up in the records; if found, the number is entered under "old cases" in the daily journal, an admission card and envelope are given to the patient and the history sent in to the examining physician. If it is a new case the name is entered in the daily journal, an admission card, address card, name card and history blank filled out by the nurse, the same running case number being entered on each. The registration nurse should obtain and enter all information called for on the front of the history blank.

The registration nurse will receive from the attending nurse the prescription and the copy given by the physician; the copy will be filed and the prescription receive a running number in red. The prescription is then given to the patient and he is told where it can be filled. At the end of the month the duplicates are sent to the office of Bacteriology as vouchers.

All new cases are to be reported daily to the Division of Bacteriology, even if they are not examined but only given a sputum jar and told to return—the name, age, address (with floor), nationality, and occupation being given.

A report is to be submitted by the registration clerk each Monday to Dr. Billings, giving the number of patients seen the week before (new, old, male, female).

If notice is received that a patient has been referred to the clinic the notice is to be held one week to await his appearance. If the patient does not come, the notices of such delinquent cases are to be forwarded to the Division of Bacteriology, with the request that they be investigated.

All deaths from tuberculosis, as reported daily by the registrar, are to be looked up in the clinic records. If found, the histories of such cases are to be filed separately.

The registration clerk will keep all institutions supplied with reference cards.

The attending nurse prepares the patient for examination, does the weighing, and helps the physician in general.

The duty of the door-keeper is to open the clinic at 8 o'clock in the morning and give all the rooms a thorough airing. During the noon hour all windows and inside doors should again be opened for airing and ventilation of all the rooms. He should assist the nurses in keeping the patients in order while in the clinic, and see to it that no violation regarding coughing and expectoration takes place.

The helpers, whose duty it is to clean the rooms, must mop the floor and wipe furniture with moist rags. The use of brooms and dusters is absolutely prohibited.

Every physician, nurse and employee, engaged in the clinic, must read these instructions and sign them to show his willingness to abide by them.

In the waiting roöm the following sign is exhibited:

No smoking.

Do not spit on the floor.

Spit only into the paper spitting cup given you.

When you cough, hold the piece of gauze to your mouth, use it also to wipe your mouth or nose.

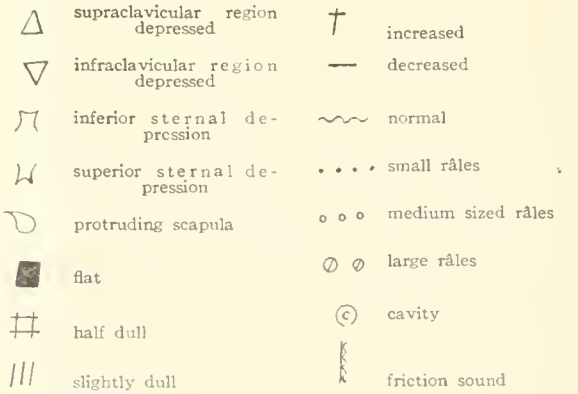
Do not throw anything on the floor.

Men will not wear hats in the clinic.

This sign is attractively gotten up, but in plain letters in English, German, Italian, and Hebrew (Yiddish), so that there can be no excuse for any of the visiting patients to violate the rules.

This examination of the patients is done as carefully and rapidly as possible in view of the fact that a large number of patients is always waiting for examination. In taking down a medical history and noting down the signs and symptoms, all of us are fond of abbreviating, and this abbreviation of terms seems to me absolutely necessary in dispensary practice. Few of us master the art of common stenography, but this does not mean that every one does not use one invented by himself, and we usually do not care whether anybody else can decipher it or not. This maxim, however, is not wise in a dispensary where it may become necessary for the history to be read by someone else than the original scribe. I therefore have ventured to compile a list of signs and abbreviations, and suggested their uniform employment to my young colleagues at the clinic. Ever since we have been able to read each others stenography.

For the benefit of the busy practitioner, or the dispensary physician who cares to make use of our hieroglyphics and abbreviations, I will here reproduce the list:



Tp.	temperature
W.-n.	well nourished
Bd.-n.	badly nourished
Em.	emaciated
An.	anæmic
a.p.d.	anteroposterior diameter
l. d.	lateral diameter
Sp.	spirometer
Exp.	expansion
V.v.	voice vibration
lft.	left
rt.	right
Fr.	fremitus
ant.	anteriorly
post.	posteriorly
lat.	laterally
inf.	infra
sup.	supra
Pl.-ret.	pleural retraction
St.	sternum
scp.	scapular
Brg.	breathing
I.	inspiration
ck.	creaking
cp.	crepitant
cr.	crackling
cs.	coarse
cv.	cavernous
dr.	dry
dt.	distant
f.	friction
g.	gurgling
h.	harsh
it.	interrupted
l.	loud
mk.	marked
mst.	moist
p.	puerile

E.	expectoration	pr.	prolonged
R.	respiration	prt.	protruding
a.	amphoric	retr.	retracted
ab.	absent	ri.	rhonchial
bl.	blowing	sb.	sibilant
br.	bronchial	sl.	slight
br.-ph.	bronchophonic	stg.	strong
br.-v.	bronchovesicular	tp.	tympanitic
c.	clear	tb.	tabular
cg.	cogwheel	w.	whistling

A number of the above abbreviations I have copied from the excellent history blank of the Winyah Sanatorium of Asheville, N. C.

One of the most important parts of the work of the tuberculosis dispensary is, of course, the hygienic education—or the training, if you prefer the word—of the patient. In private practice it is possible to give these instructions entirely orally and devote a sufficient amount of time to that purpose. In a busy dispensary practice this is utterly impossible, but a few of the most essential words of advice should be given orally even to the dispensary patient. The spoken word under such condition will certainly make a deeper impression.

To furnish the patient with the much needed information concerning his mode of life, his duties toward himself, to his immediate environment, to the physician and to the public in general, I prepared for my service at the Health Department's Clinic the following instructions:

ADVICE FOR PATIENTS.

Be hopeful and cheerful, for your disease can be cured, although it may take some time.

Obey your physician's instructions faithfully.

You may improve steadily for months, and lose it all by carelessness.

Improvement does not mean cure; therefore continue to come to the clinic as long as you are directed to do so.

Do not talk to any one about your disease, except your doctor or nurse.

Do not listen to tales of other patients, or follow their suggestions or those of others concerning the treatment of your disease.

Your spittle contains germs and is dangerous to yourself, your family and your neighbors when not properly taken care of.

When in the house always spit into a spittoon half full of water; empty the vessel into the closet at least once a day and rinse it with hot water.

When outdoors, spit in a pocket flask of glass or metal, which you clean in the same manner. If you use a paper pouch burn it after use. If you do not wish to use a pocket flask or paper pouch, use pieces of muslin to spit in, and burn them on your return home.

If you should be outdoors and not have a pocket flask, paper pouch, or piece of muslin with you to receive your spittle, expectorate into the gutter.

Never spit on the sidewalk.

Never swallow your spittle.

Handle the soiled personal and bed linen, especially handkerchiefs, as little as possible in the dry state. When soiled, place these articles in water until ready to be washed.

Do not kiss any one upon the mouth.

Always wash your hands thoroughly before eating, and clean your finger nails.

Shave your beard, or wear it closely clipped.

In the treatment of your disease fresh air, good food, and a proper mode of life are more important than medicine.

Take no medicine that is not ordered by your physician.

Stay in the open air as much as you can; if possible, in the parks, woods or fields.

Do not be afraid of cold weather.

Avoid draughts, dampness, dust, and smoke. Dust and smoke are worse for you than rain and snow.

Never sleep or stay in a hot or close room.

Keep at least one window open in your bedroom.

Have a room for yourself if possible; if not, be sure to have your own bed.

When indoors, remain in the sunniest and best-ventilated room. The room should preferably be without carpets; small rugs may be allowed.

No dusting or cleaning should be done while the patient is in the room. Cleaning should be done only with a moist rag.

Draperies, velvet furniture, and all dust-catching materials and furniture should be avoided in the patient's room.

Wear underwear according to the season. Don't wear chest-protectors.

Dress comfortably and sensibly, and avoid garments constricting neck or chest.

Keep your feet dry and warm.

Avoid all unnecessary exertion. Never run, never lift heavy weights.

Never take any kind of walking, breathing, or other exercises when you are tired, nor take them to the extent of getting tired. The kind and amount of exercise which you should take will be prescribed for you by your physician.

Go to bed early, and sleep at least eight hours.

If you have to work, take every chance to rest that you can get.

Keep your body clean, and take a warm bath once a week; take cold douches or cold baths according to the directions of your physician.

Take a half hour's rest on the bed or the reclining chair before and after the principal meals.

Avoid eating when bodily or mentally tired, or when in a state of nervous excitement.

Eat plenty of good and wholesome food. Besides your regular meals take a quart of milk daily, from three to six fresh eggs, and plenty of butter and sugar, provided this does not disagree with you.

Eat slowly; chew your food well; avoid anything which causes indigestion.

Keep your teeth in good condition. Use a toothbrush and toothpick after each meal.

See that your eating utensils are thoroughly washed after use.

Do not smoke and do not drink liquor, wine or beer, except by special permission; but drink plenty of good, pure water between meals.

See that your bowels move regularly every day.

Report to the clinic when directed. Report immediately if you have fever, indigestion, diarrhœa, constipation, pain, increased cough, or reddish expectoration. If you are too ill to come to the clinic, send word.

If you should have a hemorrhage do not become alarmed; keep quiet and send for a doctor, or notify the clinic.

Try to control your cough as much as possible. You should only cough when you have to expectorate.

Cover your mouth with your hand or handkerchief when you cough.

Avoid all bad habits.

If you are in doubt about any matter concerning your treatment or mode of living, ask your doctor.

When the physician prescribes a rest-cure, either in bed or on the reclining chair, it must be carried out either on the veranda or in front of the open window.

Your cure depends upon obeying all instructions faithfully.

FOR GENERAL INFORMATION OF THE CONSUMPTIVE AND THOSE LIVING WITH HIM.

If the matter coughed up be properly destroyed, a person suffering from consumption may frequently not only do his usual work without giving the disease to others, but may also thus improve his own condition and his chances of getting well. If all the above precautions are attended to there is no danger to the healthy in the ordinary intercourse of the family or society.

This leaflet has been translated by the Department's translators into German, Italian, Hebrew (Yiddish), and later on will be translated into Bohemian, Russian, and probably into Chinese. Each patient is given such a leaflet with the request to study it carefully, and for his own interest follow the instructions religiously.

In a busy dispensary service it is necessary to simplify the prescribing of medicine as much as possible. In order to do this with justice to the individual opinion of each of the attending physicians we recently arranged a conference among ourselves at which we came to a most agreeable understanding. The result will be, I hope, a judicious economy and a saving of time, without, however, neglecting that important maxim in modern phthisio-therapy: Treat the consumptive individual and not the disease.

As a valuable adjuvant in aerotherapy we teach our patients simple breathing exercises and in certain cases add the pneumatic cabinet treatment and ozone inhalation.

Our clinic was formally opened on March 1.

Since then, up to May 15, 794 patients (561 male and 233 female) have applied for diagnosis and treatment; 1,350 visits have been made afterward by them (977 male and 373 female), some returning once, some twice weekly. Thus, the total number of visits made to the clinic by ambulatory patients was 2,144, or a daily average of 33.5. The number of cases under treatment or observation on May 15 was 486. Out of the 794 patients the first sputum examination revealed the presence of the bacilli in 155; in 331 the first examination of the sputum was negative, but the symptoms and physical signs were evident enough to make the diagnosis positive. Seventy-two patients have been referred to sanatoria or special tuberculosis hospitals; 164 were referred back to their private physician or to general dispensaries as non-tuberculous. Sixty-eight patients who applied to the dispensary gave wrong addresses and could not be found by visiting nurses or inspectors. Of these 68 patients 55 were positively diagnosed as suffering with pulmonary tuberculosis.

In glancing over these figures, representing the work of only two months and a half of our clinic, some interesting and valuable lessons can be learned. The first of all is the very large number of patients who applied to a special tuberculosis dispensary for treatment. It shows that the public is wide awake to the importance of an early diagnosis and timely treatment. A second interesting factor revealed by these statistics is a corroboration of what is taught by all modern masters in medicine, not to rely on the bacteriological examination alone nor to wait for the inauguration of treatment until the bacillus is in evidence. No less than 775 specimens from the same number of patients have been examined and two smears made of each specimen; only in 155 cases was the bacteriological examination positive. The third interesting fact revealed by these statistics has a bearing on the social aspect of the tuberculosis problem in a peculiar way. You have heard that 68 patients who applied at the clinic gave wrong addresses, and that of these 68 persons, 55 had been found tuberculous. The reasons these patients have had for not giving the correct addresses may have been manifold, but I am convinced that the most frequent one of all was that they did not wish their neighbors, friends, relatives, or boarding-house keepers to know that they were suffering from consumption. Let us hope that with a continued educational campaign and increasing sanatorium facilities of treating these most unfortunate ones, the fear of being detected as consumptives will gradually disappear.

In reporting the unusual amount of work of our clinic done in so short a space of time, I feel in duty bound and am much pleased to acknowledge the devotion and untiring zeal to the work manifested by the attending physicians, Drs. Adams, Canfield, Cherry, Cotter, Fitzgerald, Karmiohl, Maloney, Maroney, Rogers, and Simpson, and the nurses Mr. Henry J. Mittell, and Misses Belliss, Burke, and Farquharson.

You will have noticed that I have said nothing about the results obtained. I do not believe we have cured many; the time has been too short. A goodly number of the patients have increased in weight and their most distressing symptoms have disappeared; the physical examination also indicated improvement. At some future date we hope to be able to publish some more complete and accurate statistics concerning the results.

The modern tuberculosis dispensary can fulfil its mission only in a perfunctory way if, besides medicine and advice, it is not able to provide for its indigent patients also such food substances as are essential in the successful dietetic treatment of pulmonary tuberculosis. How necessary this is I do not believe I can better demonstrate to you than by relating an anecdote from my own experience. In my younger days I was attached to a dispensary, and among our patients were a goodly number of consumptives. A young man, coming to my class, suffering from a moderately advanced pulmonary tuberculosis, complained to me of having no appetite. I prescribed for him what I considered a good tonic and advised him to improve his appetite by moderate outdoor exercises. A few weeks later I saw him again; the scales revealed an additional loss in weight. I asked him whether his appetite had not improved? The reply was in the affirmative. He saw the puzzled expression in my face, and said: "Doctor, it is not your fault that I did not gain in weight; you improved my appetite, I could eat a whole lot if I only could get the food. Being out of employment and having but little money left, I have lived on milk and crackers ever since you improved my appetite." This might sound humorous, but it is really pathetic, and shows how much it is necessary for a modern tuberculosis dispensary to have something else to dispense besides advice and medicine. Whether this something else shall be milk or eggs, or entire meals through the aid of the diet kitchen, must depend upon the facilities and means placed at the disposal of the dispensary.

There is one more point to be treated in relation to the administrative side of the tuberculosis dispensary and which, in a manner, applies to institutional treatment of consumptives in general. I refer to the selection of the staff, and the remuneration of the attending physicians. The first requisite for any physician who comes in daily contact with tuberculous patients for hours at a time should be good health and a strong, vigorous constitution. I speak earnestly and feelingly on this subject, for in my career I have had the misfortune to lose a number of dear friends and brilliant colleagues who were either overtaxed in their work or not vigorous enough to resist the invasion of the bacilli. Many have fallen victims and, as we all know, the list of martyrs is not yet closed. A number of our brightest young men, who served recently on the staff of the Bellevue Hospital, lost their lives through becoming victims of a disease which we consider so eminently preventible. The lesson which we should learn from this sad experience is that where tuberculous patients are treated the utmost precaution should be taken. Not only should the patients themselves live and be treated where there is plenty of light and air and where everything is as sanitary as possible, but the physicians who treat them should also have quarters where there is plenty of light, plenty of good air, and all the sanitary comfort which they need so much.

No physician predisposed to tuberculosis should make tuberculosis a specialty, except when he can live in a health resort, can take life relatively easy, and be able to take just as much care of himself as he would of the patient he is most interested in. A middle-aged physician whom I treated for incipient tuberculosis for a number of months, applied to me the other day for a position as attending physician to our clinic. I refused to entertain the proposition and told him plainly why, and he felt grateful for it.

Our present staff is composed of twelve vigorous young men, all of whom have had considerable hospital experience and have been in general practice for some time. This brings me to the other part of the question. These gentlemen devote a good deal of time to the service at the clinic, and the community at large profits through their taking care of

and educating a very large number of ignorant tuberculous patients who otherwise would constitute centers of infection. By a number of them being cured and made breadwinners instead of being allowed to die or to become burdens to the community for a number of months, the community gains financially. Would it be more than fair and just that these ten young men, and all those working in similar institutions, should receive a proper compensation for the valuable service they render to the community? It is with a feeling of considerable pride that I make the statement that our distinguished Commissioner of Health, Dr. Thomas Darlington, the director of our clinic, Dr. Hermann M. Biggs, and my colleague, Dr. John S. Billings, Jr., are earnestly working to make the position of attending physicians to our pulmonary clinic a salaried one.

In conclusion permit me to give you a little bit of history of tuberculosis dispensaries. The French were the first to inaugurate their *Dispensaire antituberculeux* in Lille; Professor Calmette being its founder. Next came the Germans with their "*Polyclinik für Lungenkranke.*" Throughout Europe and in some of the South-American republics there exist now numerous tuberculosis dispensaries devoted exclusively to the treatment of consumption.

During the military occupation of Havana, the Chief Sanitary Officer, Major Gorgas, U. S. A., and Dr. C. L. Furbush, Acting Chief Sanitary Officer, had established the "*Dispensario Especial de la Sanidad*" for the purpose of treating tuberculous patients only. Great credit is due to the medical department of the U. S. Army for the inauguration of this phase of the antituberculosis crusade in Cuba. I understand that this dispensary is still in operation and doing good work under the auspices of the local government.

The first dispensary class in the United States, devoted exclusively to the treatment of tuberculosis was inaugurated some nine years ago by Dr. Edward J. Birmingham of this City, at the New York Throat and Nose Hospital. In 1896 it was my privilege to take charge of one of the classes there, and I had much opportunity to see the great good which could be done by the conscientious treatment of the ambulatory consumptive poor in this city. I began to look about for the multiplication of this kind of work, but my humble efforts met only with partial success.

Some three years ago I asked one of our most distinguished professors of medicine, who was at the head of a large outdoor department, whether he did not think it wise to inaugurate a special tuberculosis department and thus not only divide the labor, but remove possible sources of infection from other patients, and at the same time do greater justice to the tuberculous invalids visiting that great dispensary? The reply was cordial but discouraging. The distinguished professor did not believe in dividing the classes, he did not see any necessity for it, and also feared that the teaching of the students attending the dispensary would be less general and less thorough.

A year later a renewed attempt was made in the same direction by a younger man who was more fortunate than I. He honored me by a few visits to ask me how he should proceed in order to establish a tuberculosis department at the very same place where I had failed. It was a great delight to me to give advice, and thus to be indirectly helpful in this work which I had longed so much to do; and like all good, truly great and noble men, the distinguished professor, above referred to, having by this time realized the value—nay, even the necessity—of such special tuberculosis classes, not only gave my young friend all the necessary facilities for inaugurating such a service, but gave his financial as well as his moral support to the enterprise.

To-day, before this distinguished gathering, I have the honor to represent the first municipal tuberculosis dispensary of this great city called into life by the untiring effort of Prof. Hermann H. Biggs, the master in preventive medicine. Now we shall listen to a symposium on tuberculosis dispensary work. You will hear of the admirable and noble work done by the Vanderbilt, the Bellevue, the Gouverneur, the Post-Graduate, the New York Throat and Nose and other dispensaries, serving not only as centers for the treatment and education of new patients and as clearing houses for patients to be selected for sanatorium and hospital treatment, but also as centers of control of all such patients as have been discharged from sanatoria, hospitals and homes and who still need to be kept under observation. Other American cities—Boston, Baltimore, Philadelphia, New Haven, Scranton, Minneapolis, Chicago, Worcester, Providence—have also started special tuberculosis dispensaries, and are doing admirable work for their ambulatory consumptive patients without means.

While there is much to be done yet in our own metropolis in the improvement of the housing of our honest laboring population, much in the establishment of sanatoria and homes for the institutional treatment of our consumptive poor, the establishment of seaside sanatoria for tuberculous children, and the establishment of agricultural and horticultural colonies for the cured tuberculosis invalids, the work done in our tuberculosis dispensaries marks an epoch in the crusade against tuberculosis of which the City of New York may well be proud. Now let our city fathers and philanthropists come to our help and aid us in maintaining and enlarging this important field for the relief of suffering humanity.

DIETETICS IN SUMMER DIARRHŒA.

By BENJ. EDEL HELPRIN, M.D.,
BROOKLYN, N. Y.
LATE SENIOR RESIDENT PHYSICIAN, THE NEW YORK INFANT ASYLUM AND OLD MARION STREET MATERNITY.

The question of dietetics is one which the physician is very frequently consulted upon, and, aside from that, his vigilance is often required to counteract the deleterious sequences affectionate—not intelligent—nursing may have erred in.

All recognize that a diet, no matter how suitable ordinarily, becomes unsuitable, even a direct menace to an infant in ill health. A careful study of the particular needs of each charge cannot thus be too strongly emphasized.

To our infants of a year or more, conditions being favorable, it is customary to allot thirty-two ounces of milk in the course of the day's feeding; this is usually apportioned into four feedings, and eight ounces at a feeding. When deemed advisable, any of the so-called "baby foods" may be safely added.

The milk, preferably, should be Pasteurized by being heated to about 167° F. The entire day's nursing may be thus prepared, placed on ice, and from time to time, as each feeding is due, the bottle containing the apportioned quantity is placed in a receptacle of hot water and retained till quite well warmed: an infant's stomach cannot tolerate cold ingestions.

But when the child is ailing the all-important problem is: what foods can be best digested?

The great indicator as to the suitability of the diet is the intestinal condition. When the mother re-

ports any variation from the normal yellow stool, the question of diet should immediately arise.

A frequent error is to treat the diarrhœa, though the intestines may be absolutely innocent, and by plying drug after drug into the system the deleterious after-effects are heedlessly forgotten.

With the approaching summer months and mindful of the variegated experiences during previous epidemics, the practitioner's outlook is for the dread diarrhœas so fatal to his infant patients, yet, treated with a thorough regard to the salient points governing the medicinal and, more especially, the dietetic treatment in the various forms of this malady, one's failures should be but infrequent.

Dr. Charles Gilmore Kerley of the New York Polyclinic, to whose patient teachings and numerous helpful suggestions I am gratefully indebted, strongly emphasizes the point: "Look to the feedings!"

In a most interesting and instructive brochure on the subject*, he states: "Summer diarrhœa differs from many other ailments of early life in that there is no tendency for it to get well of itself. It is a disease which must be treated upon the appearance of the first symptom, and treated vigorously." And those who have devoted their efforts to the especial diseases of children recognize the importance of this.

Very frequently the paramount point in the treatment is proper dietetics. From this standpoint our ordinarily-allotted thirty-two ounces of milk for the day's nourishment, must now be subplanted by some modified milk diet, more easily digested.

The duration of the disease, the condition of the intestines, and particularly, the nature of the stools, which must always be carefully and frequently examined by the physician personally, will suggest, largely, the most suitable diet.

The presence of curds in the stools, or vomiting clearly indicate too much milk; an intestinal rash, the "hunger-cry" or a febrile condition; in fact, any untoward condition responsible for persistent abnormal stools, if the intestines be not primarily at fault, gives the physician strong presumptive evidence of the necessity for dietary change.

For a day, at least, albumen water now is most advisable; the strength of this preparation may, of course, vary with the individual need, but the usual method is simply to add the white of one egg to each eight ounces of sterile water; about five grains of ordinary sodium chloride makes this more palatable, and the addition of a little brandy or whiskey is salutary both for its stimulative and astringent effect; the quantity and intervals of feeding are best judged by a study of the case.

On the morrow our infant patient may be tried on what we term "Barley-Water No. 1" prepared by adding a heaping tablespoonful of any reliably prepared barley flour to each pint of sterile water, and boiled for from twenty to thirty minutes; just sufficient milk-sugar should be added as to make the food pleasant to the taste. Should the intestinal condition warrant it, this preparation may be doubled by an additional quantity of the flour.

It is most advisable to still withhold milk for a little while, and when the barley-water becomes monotonous and distasteful, another useful alternate which has given the utmost satisfaction in several discouragingly obstinate cases is the following: Two tablespoonfuls of ordinary flour in an agate dish retained in an oven till the flour is well browned, then "blend" or dissolve in a little cold water; this is now gradually added to, and stirred in two pints of water while boiling. This may be given in three-ounce apportions, and ten feedings. One-half drachm, gradually increased to a drachm and a half, of condensed milk, can, in the course of a day or two, be judiciously added to each feeding. Other preparations of the same class include corn-starch and granum.

Some tonic is always indicated to tide over the weakness concurrent with the reduction or exclusion of the milk, and any suitable tonic may be included in the feedings, or given independently.

A point to be impressed is the necessity to wake the child for each medication and feeding, as there is generally an apathetic disinclination to take even the much lessened nourishment; the rule, therefore, as to quantity and number of feedings must be set aside and the patient coaxed, or even forced to ingest as much as possible.

When the physician deems it advisable to introduce modified-milk formulary he should proceed very cautiously, and but a very few ounces of milk is at first permissible, and gradual increases made only under very favorable conditions; frequently, condensed milk will prove the more satisfactory.

Obstinate cases always suggest gavage, and this has proven the salvation of many an infant when formulary have otherwise yielded but discouraging results. I have again to refer to a brochure on the subject* by Dr. Kerley which renders many valuable suggestions.

Of late years experiments have been made in institutions and private practice with numerous scientifically prepared aids to difficult feedings, and many of them are at least worthy of a trial, but as soon as the digestive functions are restored to the normal their discontinuance is the more advisable.

It may be quite some time before milk alone can be safely advised, and frequently the entire process may have to be started all over again, but the victory at last gained will be well worth striving for, even amidst seemingly discouraging failures at first.

In conclusion, just a few lines on the co-incident medications as an adjuvant to the dietetic treatment, principally the diarrhœa and vomiting. Throughout the treatment not a drop of any opiate is at any time justifiable save as a very last resort.

Castor oil has been regarded as the panacea for all ills and pains man is heir to, and in conjunction with very moderate doses of calomel has proven effective in controlling the vomiting due simply to an overloaded intestinal tract, and in ridding this tract from some noxious irritant which may have caused the diarrhœa, though the laity very often cannot seem to understand why such catharsis be employed in an already active condition.

A useful prescription to hold the diarrhœa in check is:

℞ Bismuthi subnitratis ..... ʒv
Bismuthi salicylatis ..... gr. xii
Syrupi rhei aromatici..... ʒiii
Aquæ q. s.....ad ʒiv

usually given in drachm doses every two to four hours. A modification of this is suggested by Dr. Kerley, and its merits have been proven in quite a number of our cases:

℞ Bismuthi subnitratis ..... ʒv
Sulphuris sublimatis ..... gr. xxx

divided in about thirty powders, each given in a tablespoonful of water every two hours; its effect is soon evidenced, but it is best continued for some time.

Colonic irrigations are also very efficient when there is offensive odor and mucus, and when blood is present. A high rectal, saline, or soapsuds enema, about three pints at 110° F., may be tried; the ad-

*"The Treatment of Summer Diarrhœas in Infants," Charles Gilmore Kerley, M.D., *The Medical News*, August 4, 1900.

*"Gavage in Obstinate Vomiting," *Archives of Pediatrics*. February, '92.

dition of a little tannic acid increases its value, or olive oil or glycerin may also prove effective; the buttocks should be compressed for at least five minutes before the enema is expelled.

475 Stone Avenue, Brooklyn.

CLINICAL NOTES ON THE MAMMARY GLAND, WITH REPORT OF FOUR CASES OF SOMEWHAT UNUSUAL INTEREST.

By THOMAS H. MANLEY, PH.D., M.D.,
NEW YORK.

The functional and organic diseases of the mamma in the female are always a subject of great interest, because of their frequency and often complicated character. Lying so near the surface, too, the organ is readily accessible for various modes of treatment; nevertheless, strange as it may seem, there is no secreting structure of its importance about which so little is known, of its definite anatomy and physiology.

And hence, why of late, in dealing with its lesions, we so widely depart from the well-established rules of procedure here and sacrifice only too frequently an entire organ when often but a limited area of it is the seat of pathological changes.

Were we but to recall that the breast is an essential constituent of the sexual system and that its supply of nutriment to the new-born is but *one* of its important functions, we would longer hesitate and weigh well the consequences before we strip it from the walls of the thorax.

The following four cases of mammary disease came under my care during the past year at the Metropolitan Hospital service:

Case I.—*Protracted Lactation of Twenty-four Years' Duration—Galactorrhœa.*—Patient married, forty-one years old, of good physique, usually enjoyed good health, admitted to hospital November 12 for nephropexy, right kidney. It was while under my care here that she complained of her bosom being almost constantly wet from a flow of breast milk.

She stated that she was first married at the age of seventeen years. Ten months after marriage was delivered of a seven-months infant—now grown up. She later had two, still-born. At thirty she was a widow; two years later was again married. Her last child was born on the night of the Blizzard, March 12, 1888. She said, that since her first-born she has had a continuous flow of milk, during the intervals of conception, during her widowhood, and since remarriage. I can find no parallel case on record; there is one recorded of six years, one of nine years, and one of fourteen years; in this latter instance, the woman nursed her grandchild, after thirteen years' interval from her last confinement.

My patient had regular, but scanty menstruation; had used no prevention to conception. Her child by her present husband—a man younger than herself—was premature and still-born.

By squeezing the breasts on one occasion, she removed nearly six drachms from both nipples. The secretion presented the ordinary physical qualities of the mammary secretion. It was of feeble acid reaction, sp. gr. 1.038. Under the microscope, it was seen to be composed rather of the characters of colostrum than the normal secretion. The fat globules were larger and in places clumped; colostrum cells were numerous; epithelial cells, more or less granular or vacuoled, were scattered over the field, with a few well-defined pigmented casts of the acinous tubules; granular material and a few very large flat epithelia of the mammillar orifices were found.

It was interesting to note in this remarkable case that from the time this physiological waste begun, though she yet conceived she was unable to carry a child to term; that the first, though it survived, was premature, it being evident that this leak at the mammæ rendered ample intrauterine sustenance of the fœtus impossible.

Case II.—*Lacteal Fistula.*—Patient twenty-three years old, brunette rather frail build, had one child, two months old. Came under my care in May, 1903, for treatment of an abscess that would not heal. Five weeks previously had an abscess of the right breast opened. It had since been irrigated, packed, and drained. Of late, the discharge from it was large, in spite of the various local remedies employed.

On inspection it was found that a very deep incision had been made, not along the radiating reservoirs of milk ducts, but diagonally through them, and hence the flow of milk was diverted from the nipple to the large fistulous opening, from which it flowed very freely when the other breast was being sucked by the child. After removing all tamponing, and by the employment of firm compression, the fistula slowly, but completely closed.

It is rare that we observe lacteal fistula after lancing an abscess in acute mastitis, because in most cases it lies superficially, and so points that it may be freely opened without penetrating deeply into the galactiferous ducts, but when the pus is deeply lodged in the parenchymatous structures, if caution is not observed in carrying the incision in the same axes as the milk ducts, a very troublesome fistula may result. There are some of these cases recorded wherein the patient had to bear with the pain and inconvenience until weaning, every description of treatment failing to close them.

Case III.—*Adenofibroma of the Breast.*—Patient referred to me by Dr. Meyer Jackson. Age forty-two, married twenty-five years, never had a child; menstruates regularly; enjoys good health; fine physical development, prominent bust. Came under my care November 12, 1903.

She reported that during the past two months she had occasional darts of pain in her right breast, being most intensified before her catamenia. Had consulted a physician who took a rather gruesome view of her case and referred her to a surgeon, who recommended the immediate amputation of the whole breast with a clearing out of the axilla, as the lymph nodes here were distinctly tumefied. To this she demurred emphatically. She was visited later by Dr. Jackson, with whom I first saw her.

She impressed me as a woman of an exceptionally vigorous constitution and a strong will. There was no shade or trace of the cachexy of malignant disease. There was no family history of malignancy, no loss of flesh, no pallor, no melancholy.

She only insisted that she wanted an operation done, but we "must not remove her breast."

Now her chest was stripped anteriorly and the right breast exposed freely as she sat in a chair. The organ was large, with a deep adipose investment, fairly firm, and well-formed for one of her age. On the most careful and repeated manipulation of the glandular structures of the organ, no distinct tumor could be delineated; only a dubious tumefaction, it was thought, could be elicited. But the superficial axillary nodes were distinctly tumefied, and she said that the pain radiated from the nipple toward the arm-pit.

Our examination was indeed but negative; though, in order to be doubly certain and to gratify her wish, as this involved no serious danger, we decided to make an exploratory incision the following day.

After she was placed on the operating-table, lying flat on her back, under full ether narcosis, we were struck by the presence of a well-defined and somewhat conical eminence standing well out above and

to the external border of the mammillary areola. It was remarkable to now note, with the body prone on the back, how clearly a tumor could be palpated which the day before completely eluded us.

Now a long, free incision through a very thick layer of fat exposed the aponeurosis; this divided carefully, exposed an encapsulated growth about the volume of a goose egg. It was of a deep crimson color and of loose consistence; in a moment, rolled out with scarcely any loss of blood. The features of this case which may be well emphasized are notably two:

1. Why on earth remove a mamma, strip the chest wall, and deform a woman for an encapsulated or, indeed, a tumor of any kind, unless a promise of permanent cure can be made? Neither did we remove the swollen nodes in the arm-pit, and possibly, had one been removed the microscope would have revealed epithelial element in the stroma; but that proves nothing at all, as I have lately found in some research work along this line, that true *histological, glandular, secreting* elements may be found in the *normal axillary nodes*.

In this case the initial pathological changes were in *one lobe* only; hence its enucleation was at once the simplest procedure imaginable; the line of attack only must be in the right direction.

2. The next feature is the position of the patient. I have recently observed that Prof. Charles F. Wainwright examines for cardiac lesion with the patient on his back, using *inspection* rather than *audition*, and so we will often note that *inspection* of the patient in the dorsal position will often avail us when the tactile exploration will fail, not only on the thoracic, but the abdominal areas as well. For example, in a case which passed a ten-week ectopic pregnancy of the right tube of Fallopius, in the Metropolitan Hospital last week, Dr. Jackson and myself utterly failed by the hand distinctly to delineate a mass; on her back on the operating-table the tumor stood out very clearly in the right flank. Incision directly over it brought the massive, soft blood-clot and ruptured tube into position for removal. I would, then, specially urge the importance of *attitude*, the *dorsal position*, on a hard, flat surface, as an aid of great value in physical diagnosis of neoplasms or tumor-like formations of dubious origin or existence.

Case IV.—*Primary Scirrhus in the Axillary Nodes.*—Patient, female, sixty-two years old, careworn, emaciated, and anæmic. No family history of malignancy. Feeble constitution; had six children. First noticed lump in arm-pit six months ago. Later it enlarged and became painful on moving the arm. Now has a scirrhous mass about the size of a hen's egg in the left axilla. Besides, another scirrhus within a month has appeared in the breast, just above and to the outer side of the areolæ, over the course of Creighton's glands of the integument. This latter nodule is movable, and confined to the integument along the axillary line. Primary scirrhus of the axillary nodes is rare, though it is common enough, as a secondary affection in scirrhus of the breast. Of this Sir James Paget said: "I have seen primary scirrhus-cancer in the axilla and cervical lymph glands. Cases sometimes occur when the disease in the glands may be so nearly coincident with that in the organ to which they are related that we may believe the gland cancer to be primary, though not alone, and sometimes the disease in the gland greatly preponderates over that in the organ, though its primary seat may be in the latter."

By a deep dissection, the hard, lobulated mass was well liberated from the axillary vessels and removed; the nodule in the mammary integument was dissected out.

The modern surgical treatment of mammary scirrhus calls for the removal of the tributary lymph nodes in the axilla, though like many other innovations it yet remains an open question whether this procedure in any manner retards the recurrence of the disease in other situations.

Just what part the lymph system plays in malignant disease is by no means yet clear, because neither its exact morphology nor its purposes in the economy are at all well understood.

Creighton, after more than twenty-five years' research in the finer anatomy of the breast, confesses his inability to inject the lymph vessels. Zappy's display of the mammary lymph vessels, so faithfully copied by several anatomists since his time, has recently been declared to be inaccurate. We have all read much of the lymph vessels, but who has ever been able to demonstrate them under the naked eye?

FALLACIES IN VITAL STATISTICS.

By F. L. WACHENHEIM, M.D.,
NEW YORK.

Modern Sociology has endeavored to prove itself an exact science by incorporating its results, whenever at all feasible, into statistical forms; the attitude of the general public being exemplified by the great and growing interest taken in our decennial census. Now, while the desire for the mathematical demonstration and numerical tabulation of collected facts is a most encouraging phase of the true scientific spirit, the blind faith with which statistical evidence is popularly regarded calls for a word of warning. It is, indeed, more than probable, that the greater part of these stately arrays of figures, in their present form, is rendered almost worthless by the inclusion of no end of fallacies; the investigator is compelled to subject his tables to the most patient and searching scrutiny, if he would not be led into a maze of erroneous deductions.

Vital statistics, especially, have become a veritable hobby, not only with physicians and sanitary boards, but with the public at large. In every city and State the deaths from the various causes are more or less carefully totalled, a synopsis of these reports is scattered broadcast through the medium of the daily and medical press, whose readers assiduously compare the rate per thousand inhabitants of their own community with that of their neighbors and rivals. I pass over the absurd attempt, often made, to furnish accurate statistics of births; in this country, at last, the enforcement of the various laws concerning the registration of births is little more than empty pretense; the city of New York, whose populace is rather more than ordinarily prolific, until recently regularly reported a birth rate rather lower than that of Paris. The best proof of our deficiencies in this respect is afforded by the ridiculously low figures in the scanty American statistics of illegitimacy; most of the illegitimate births are simply not reported at all. As to mortality reports, a study of even those most reliable will suffice to convince us that vital statistics are a notably conspicuous example of tables that are quite useless as a basis for profitable conclusions, unless subjected to a thorough, critical investigation. It would not be possible, in a brief essay, to discuss all the sources of error in detail; a consideration of a few of the most glaring will, however, not be without interest.

The basis of all vital statistics must be an accurate estimate of the total population. Unfortunately, in the United States, the decennial enumeration is rarely made with anything approaching true correctness; repeatedly, as in 1870 and 1890, the Government tables have been thoroughly vitiated by gross negligence on the one hand, and positive fraud on the other. The census of 1890 may, indeed, be justly regarded as a statistical calamity, the ambitious scope and gigantic scale of its vital reports giving a painfully misleading impression as to their real value; the intentional and unintentional errors of said enumeration have caused many of its tables of mortality to be just so much waste paper, a positive impediment to scientific progress. I give an example:

		1890	1900
City of Omaha	Population	140,452	102,555
	Deaths	1,397	1,382
	Per 1000	10.0	13.5
Boroughs of Manhattan and Bronx	Population	1,515,301	2,050,600
	Deaths	43,378	42,955
	Per 1,000	28.6	20.9

One would infer that sanitary deterioration had kept pace with the decline of general prosperity in Omaha, and that almost Oriental conditions had at last roused the good New Yorkers to the merits of a thorough housecleaning. There is, however, every reason to believe that the population of Omaha in 1890 was exaggerated to the number of about 40,000 by the same methods that were exposed in St. Paul and Minneapolis, and which it is not necessary to describe further. It was proved, in addition, that in Manhattan, and Bronx (Old New York) carelessness of the enumerators and "practical politics" omitted about 200,000 inhabitants. If we apply an appropriate correction to the figures given above, the rate per 1,000 for 1890 becomes changed to Omaha, 13.9; Manhattan and Bronx, 25.3; thus both communities show a moderate improvement for the decade.

The two given instances are mere selections from a large number. It would not be difficult to establish the same defects in the returns for a number of other Western cities. Of course, the statistics of the States containing these cities are also quite worthless.

For the sake of convenience in discussion, I am treating the census of 1900 as approximately accurate; at any rate, no glaring errors have as yet been exposed, and the reports show a praiseworthy endeavor to indicate weak spots by a method of self-criticism.

A misleading factor in the mortality tables of large cities, raising their death rate above the true figure, is introduced by the presence of hospitals and other institutions which are often, in part at least, the refuge of strangers from the country or abroad. The possible extent of this fallacy is most clearly shown in the detailed reports of the Department of Health in the city of New York, where the death rate for the suburban, and exceptionally salubrious Borough of the Bronx regularly exceeds that for the overcrowded, and in many respects, very insanitary Borough of Manhattan. These reports do not fail to make due mention of this circumstance, and correctly account for it as caused by the presence in the Bronx of institutions, such as hospitals for consumptives, and homes for incurables, almost entirely devoted to residents of Manhattan. Similar conditions undoubtedly apply to the city as a whole, in comparison with the remainder of the State and the country at large, for the city of New York retains the greatest portion of the less robust element of our flood of immigration, and is a favorite haven of refuge for the vagabond population of the whole United States during the winter months. Even in smaller towns the extent of the above factor defies exact calculation, the more so since our populace is somewhat of a roving disposition, and the question of actual residence often indeterminable.

The census reports for 1900 state the death rate for New York at 20.4 per 1,000, and that of Chicago at 16.2 per 1,000, a ratio of 1.26 to 1.00 in favor of the latter. It would be rash to conclude from these figures that sanitary conditions are 26 per cent. worse in New York than in Chicago. We must not overlook the fact that the newer cities of the West are composed of a picked population, as regards both age and general vigor.

When we compare the inhabitants of the two cities with respect to ages we observe the following:

	NEW YORK.	CHICAGO.
Group I.—Population under 5 yrs. of age	11.6 per cent.	11.2 per cent.
" II.— " between 5 and 44 yrs.	72.5 "	74.2 "
" III.— " of 45 yrs. and over	15.9 "	14.6 "
Total	100.0 per cent.	100.0 per cent.

The second group, consisting of individuals of the ages most resistant to disease, is in excess in Chicago, while the proportion of elderly persons is quite low. The extent to which the death rate varies with age is shown by the figures for the United States as a whole: Group I, having a mortality of 34.6 per 1,000; group II, of 6.1; group III, of 28.6. It is evident that the preponderance of the second group will reduce the death rate of Chicago as a whole. Calculation shows that if the population of New York were of the same age as that of Chicago, the death rate in the former would be only 19.8. The ratio of New York to Chicago is therefore only 1.22 to 1.00 on this rough correction. If we compare the second groups alone in the two cities, we find the respective death rates to be New York, 8.6; Chicago, 7.4. In this class, the one presenting the fairest test of the influence of sanitary surroundings, the ratio is only 1.16 to 1.09, or 18.8 to 16.2.

Let us turn to the rôle played by the quality of the respective populations of these communities. The relative inferiority of New York may undoubtedly be attributed, in part, to the inertia of the lowest order of immigrants, who are apt to halt at their point of debarkation. Something must also be said on the subject of racial differences, which are greater than one might suppose. I give below the racial proportions per 100,000, the death rate for each component per 1,000, and the excess or deficiency of deaths per 100,000 in New York; the last calculated on the mortality among the native stock:

RACE.	NEW YORK.	CHICAGO.	DEATH RATE.	N. Y. + OR —
Native	21,000	21,000	15	..
Germanic	28,000	28,000	15	..
British	5,000	6,000	16	—1
Celtic	22,000	13,000	21	54
Scandinavian	2,000	11,000	12	27
Slavonic	5,000	14,000	13	18
Italian	7,000	2,000	20	25
Russian-Jewish	8,000	3,000	12	—15
Total	100,000	100,000		108 per 100,000
				1.08 per 1,000.

I have given the populations in round numbers, as any pretension to greater accuracy would be illusory, for nationality and race do not always coincide; the figures are, however, sufficiently striking as given. Note the excess of the inferior Celtics and Italians in New York, and of the hardy Slavs and Scandinavians in Chicago.

Summing up, we have seen that if the population of New York corresponded to that of Chicago in age, its mortality would drop at least to 19.8; a racial agreement would further reduce it to 18.7, an improvement in quality to equal that in the West would surely make it not over 18.0. The

net result of these investigations is that more than one-half of the supposed greater salubriousness of Chicago is purely imaginary, and based on the uncritical use of statistical data; furthermore, generalizing from the above, it is plain that, if we wish to employ the death rates of towns as indices of their relative healthfulness, they must be compared age for age, race for race, and with due regard to that somewhat vague component, the physical condition of the individual; the crude tables as they stand, are absolutely worthless, and give rise to every sort of erroneous conclusions.

Let us now pass on to the errors that prevail with regard to the relative increase and decrease of certain diseases. It is generally believed, even in scientific circles, that cancer is growing in frequency to an alarming degree; the published figures for the whole United States being as follows:

	1890	1900
Deaths from cancer	18,536	29,475
Rate per 100,000 population	29.6	38.6
Relative increase	....	30.4 per cent.

An advance of 30 per cent. would assuredly be a serious matter, could it pass unchallenged. Let us, however, apply a few simple tests: Cancer is usually a disease of advanced life. Now, the proportion of individuals of forty-five years and over has increased 4.7 per cent. during the stated decade, the natural increase of cancer might therefore be set at that figure, reducing the apparent growth to 24.5 per cent.*

Nobody seems to have felt much anxiety over the increased mortality from heart disease. There is, however, a most curious correspondence between the two affections, as tabulated:

	1890	1900	INCREASE.
Death rate from cancer	29.6	38.6	30.4
" " " heart disease	70.9	90.7	27.9

As the vast majority of deaths from the latter cause also occur late in life, the comparison is a fair one. The difference is so very small as to lead to the suspicion that the registration for 1890 is incomplete, a suspicion easily verified. From various circumstances we may consider the census of Philadelphia about equally accurate for both years. The tables for that city are:

	1890	1900	INCREASE.
Total population	1,046,964	1,293,697	..
Deaths from cancer	529	806	..
Rate per 100,000 inhabitants	50.1	62.2	24.0 per cent.
Deaths from heart disease	1,588	1,938	..
Rate per 100,000 inhabitants	151.6	149.7	—1.3 per cent.

There remains a 24 per cent. increase for cancer, while heart diseases have shown no appreciable change in ratio. It is evident that further investigation is called for, and we may begin by taking up the question of diagnosis. In the former year fifty-six Philadelphians died of unspecified tumors; in the latter, only fifty. It is the general experience that nearly all unspecified tumors are, as a matter of fact, cancerous, for the site and nature of the benign types of growth are rarely difficult of diagnosis. Adding, therefore, these "tumors" to our figures, we have:

	1890	1900	INCREASE.
Deaths from cancer	585	856	..
Rate per 100,000 inhabitants	55.4	66.1	19.3 per cent.
Rate with correction for age	..	..	14.2 per cent.

Great as the reduction is from 30.4 to 14.2 per cent., it does not tell the whole story. Could we, for example, overhaul the statistics of deaths from unspecified diseases of the stomach, we would certainly find that more cancers of that organ (the commonest seat of malignant growths) were overlooked in 1890 than in 1900, for in just this field of diagnostis progress has been conspicuous during the last decade.

*29.6 + 4.7 per cent. (1.4)=31; showing an increase of 7.6 in the rate per 100,000, or a relative increase of 24.5 per cent.

In view of the corrections indicated, it would not be surprising if, after all, the dreaded increase of this terrible affliction should be little more than a bug-bear. The apparent increase in cardiac disease has been easily eliminated; the corresponding one in malignant disease is, from its nature, not so readily disposed of, but is assuredly far less than appears at first sight.

Almost in inverse ratio to the growth of the diseases just discussed is the falling off of malarial fever, amounting in New York and New England to 67 per cent. in ten years, and within the whole "registration area" to 54 per cent. This is attributed off-hand to improved sanitation. Turning, however, to typhoid fever, our best sanitary index, we find for the same period a reduction in total mortality of only 27 per cent., despite the fact that improvements in treatment have reduced the relative death rate from this affection very materially; one might say that the number of cases of typhoid fever had remained about stationary. It is easy to show that the tables for malaria are a gigantic diagnostic blunder. In 1890 the microscopical determination of the malarial parasite was rarely made. In that year 1,351 deaths from malaria were reported from New York and New England, regions where fatal malaria is practically unknown. Modern diagnostic methods, imperfectly applied, brought the figure for 1900 down to 539 deaths (probably about 500 too many) in the same district. It is, moreover, quite safe, to say that at least 1,000 of the 1,351 deaths from malaria in 1890 should have been charged to typhoid fever; some of the supposed improvement in the former plainly belongs to the latter.

The above partial overhauling of two series of mortality tables, and the laying at rest of the ominous and flattering delusions respectively attached to them, can lead to but one conclusion. Up to the present time, all that can be said for the whole series of mortality tables, as published, is that they are plausible and create an optimistic (occasionally pessimistic) impression; of true scientific value there is hardly the faintest trace. Let us hope that some day the blind worship of the fetish of crude vital statistics will be relegated to the limbo of other pseudo-scientific superstitions. Any deductions drawn from those we have are almost certainly erroneous and a bar to real progress in this branch of medical science.

105 East Eightieth Street.

A FEW QUOTATIONS FROM SHAKSPEARE SHOWING HIS ACQUAINTANCE WITH MEDICAL AND OTHER SCIENCES.

By J. W. WAINWRIGHT, M.D.,
NEW YORK.

That Shakespeare was mentally the master of all time is more and more in evidence as we intelligently read his writings. The whole range of human knowledge, from science, anticipating research, to law and theology, is within his grasp. It is claimed that he had surely studied law, that he must have been a close student of theology—indeed, an academician, to possess such knowledge as he displays of mathematics, astronomy, and literature. We may with equal certainty claim that he had been a student of medical science, for his works contain most marvelous references to this science which it has never beed thought existed in his time, yet which reads to-day as if written by a twentieth-century scientist.

That Shakespeare was aware of the theory of the

action of antitoxin is evident from the following quotations:

Benvolio—"Take thou some new infection to the eye,
And the rank poison of the old will die."
"Romeo and Juliet," Act I, Scene II.

The search for immunity from disease began in the early days of history. In fact, Galen used the flesh of the viper as an antivenene, while Mithridates fortified himself against disease by taking all the then known antidotes. He also experimented upon condemned criminals, and finally succeeded in rendering himself and them immune to snake bite by taking the blood of animals which had been fed upon venomous snakes; Andromachus, physician in chief to Nero, as well as other notables, resorted to the same expedients. Finally Dioscorides advised those bitten by mad dogs to drink the blood and eat of the liver of the animals which had bitten them.

Those who have studied the means of acquiring immunity will no doubt be surprised to learn that the ancients had so comprehensive a knowledge of what is by most believed to be a modern achievement. That Shakespeare was in possession of this knowledge is clearly evidenced from the above quotation.

Again, it is quite certain that Shakespeare anticipated Harvey in a knowledge of the circulation of the blood. Note the following significant quotations:

Brutus—"You are my true and honourable wife;
As dear to me as are the ruddy drops
That *visit* my sad heart."
"Julius Cæsar," Act II, Scene I.

. . . . . .

Ghost—"Holds such an enmity with blood of man,
That, swift as quicksilver, it *courses through*
The natural gates and alleys of the body;
And, with a sudden vigor, it doth posset (coagulate)
And curd, like eagre (acid) dropping into milk,
The thin and wholesome blood;"
"Hamlet," Act I, Scene V.

The play of Hamlet was first printed in 1603, while Harvey made known his discovery of the circulation of the blood in 1628, although he states in his "*Exercitatio-Anatomise de Motu Cordis et Sanguinis*" that he had for nine years been demonstrating the subject in his lectures at the College of Physicians in London. Even this would, if allowed, carry him back only as far as 1619, or sixteen years after the first appearance in print of "Hamlet." "Julius Cæsar" was first printed in 1623

Again, note in "Coriolanus," Act I, Scene I.

Menenius—". . . But, if you do remember,
I send it through the rivers of your blood,
Even to the court, the heart, to the seat o' the brain,
And, through the cranks and offices of man:
The strongest nerves, and small *inferior veins*,
From me receive that natural competency
Whereby they live:"

The physiologist will be highly edified in reading this whole scene from "Coriolanus."

Now let the gynecologist ponder over the following most start ing quotation in "Winter's Tale," Act II, Scene I:

Antigonus—"I have three daughters; the eldest is eleven;
The second, and the third, nine and some five;
If this prove true, they'll pay for 't: by mine honour,
I'll geld them all: fourteen they shall not see,
To bring false generations: they are co-heirs;
And I had rather glib myself than they
Should not produce fair issue."

The master here places the age at which menstruation or puberty appears at fourteen years.

To geld his daughters, *Antigonus* would have to remove their ovaries. Can it be that this operation of ovariotomy had been performed on women before Shakespeare's time? The very thought is startling.

Sir Isaac Newton was born in 1642 and died in 1727. Authorities generally concede him to have been the discoverer of the universal law of gravitation, first brought to his attention through witnessing the fall of an apple while sitting in his garden one day during the year 1665. Through faulty application, however, of the laws then in use to explain the lunar and planetary motions, he was unable to verify the motions excepting approximately. This so disappointed him that he turned his attention to the study of color and light. In this direction he accomplished much.

William Shakespeare was born in 1564 and died in 1616, or twenty-six years before Newton was born, and yet we find in Shakespeare's "Troilus and Cressida," Act IV, Scene II, the following significant allusion to gravitation:

Cressida—"But the strong base and building of my love
Is as the very center of the earth,
Drawing all things to it."

The reference is quite sufficient to convince one that Shakespeare had a correct theory of gravitation.

Verily there is nothing new under the sun.

I have given but four instances of Shakespeare's versatility. The physician and surgeon will find many, very many, just as startling if he search for them.

177 West Eighty-third Street.

The Causes, Pathology, and Treatment of Chronic Rheumatism.—Ralph Stockman calls attention to the fact that the symptoms arising from implication of the fibrous tissues about the bladder and thorax often cause much mental anxiety to patients. In the case of the bladder the symptoms consist in dull pain and increased frequency of micturition, but they usually pass off in about a week. When the intercostal muscles and the fibrous tissues of the ribs and sternum are affected, each respiration may cause pain or discomfort, and if the respiration be deepened by effort, the pain may become acute and darting or stabbing in character. When the fibrous tissue behind the pharynx is affected, the symptoms are chiefly subjective; the patient feels as if the parts were slightly swollen, stiff, and uncomfortable; but little or nothing can be made out on inspection. It is not known whether the pains in the muscles and bones in acute muscular rheumatism are due solely to a true rheumatic infection or whether they occur with several febrile conditions. The general treatment is that of a slight feverish attack and recovery takes place in a few days. If the pains are widely spread over the body, rest in bed, light diet, saline purgation, mild diaphoretics or mild alkaline diuretics hasten recovery and give ease to the patient. Sodium salicylate, alone or with phenazone or phenacetin, greatly relieves the pain and aching; or methyl salicylate may be applied locally. The salicylates, however, do not exercise the same immediate specific action which they show in acute articular rheumatism. A hot bath, followed by a copious perspiration or a Turkish bath, with well-applied massage, if taken in time, may abort the attack. Very often in such an attack the chief site of the pain is localized in the lumbar region, shoulders, neck, chestwall, or lower extremities, and in these places, the painful area is often small and results from serious exudation. The best treatment is massage followed by passive and active movements. One thorough application may be all that is necessary. The parts are very tender, and manipulations must be begun very gently by stroking so as to get rid of the exudation and relieve tension. Little by little more pressure can be borne, first with the palm of the hand and then with the fist or knuckles. The local inunction of methyl salicylate alone or mixed with an equal part of liquid paraffine, often relieves the pain, or a ten-per-cent., solution of menthol in liquid paraffine may be used. Local irritants, such as mustard leaves, are beneficial. In the case of chronic rheumatism, treatment is much more difficult and prolonged. Massage and exercises, the faradic current, and the injection of solution of chromic acid into any of the fibrous nodules, which are clearly enough defined for this treatment, are indicated. General Massage is of no use. Treatment must be especially directed to any nodules and indurations which can be felt and to parts which are painful.—*The Edinburgh Medical Journal*, March, 1904.

THE DIETETIC TREATMENT OF DIABETES.

THE London *Practitioner* for June contains some practical considerations on the dietetic treatment of diabetes, by Dr. Robert Hutchison. In no other disease except obesity must the treatment follow so closely dietetic lines. It is sometimes said that diabetes is incurable and dieting only suppresses a symptom. The only real symptoms of the disease are wasting and weakness, the remaining symptoms being secondary to the presence of sugar in the blood, or the necessity for its elimination; and the same is true of the complications. The irritating effects of the glycohæmia are neuritis, perforating ulcer, cataract, and retinitis, while on the excretory side we have polyuria and thirst. The saccharated blood would also seem to offer a favorable nidus for microorganisms, the boils, carbuncles, gangrene, and phthisis being thus accounted for. Again, whatever be the true pathology, all observers agree in regarding diabetes as a condition in which sugar assimilation is impaired, and this impaired function can be improved by rest, and further impairment can result from its overwork. Indeed we often see patients unable to assimilate, become able to do so after the rest involved in a sugar-free diet.

By "diabetes" Hutchison means merely permanent glycosuria, waiving the question as to whether the glycosuria of the aged differs from that of the young, as from the standpoint of dietetic therapeutics the question is immaterial. All that need be said is that the younger the patient, the greater the need for continuous, energetic, and careful dieting; while the older he is, the greater the laxity that may be indulged in.

Given then a diabetic patient, the wrong thing to do is to draw up a list of non-saccharine permissibles and of saccharine unpermissibles. The first thing to do is to ascertain by a "test diet" this particular patient's "tolerance" for the carbohydrates, by giving a moderate amount of sugar-free food plus a known quantity of carbohydrate aliment (say four ounces of bread = 66 grams of sugar). At the end of three days the total daily amount of sugar in the urine is determined. If the patient excretes less than 66 grams, the deficiency represents his capacity to assimilate sugar (his "tolerance"). If he excretes 66 or more grams, the "tolerance" is zero. These two classes represent "mild" and "severe" cases respectively, and the treatment is quite different for the two groups. With the "mild" cases the limit of toleration is first to be definitely determined by varying the amount of bread in the dietary. Then an amount of carbohydrates, well within the limit of toleration, is to be allowed (say two ounces daily, if the limit be determined at four ounces). And the combination of sugar-free diet and carbohydrate allowance, is to be maintained as long as weight and general condition remain satisfactory. But about twice a year a strict dietary is to be enforced to give the carbohydrate assimilating functions a complete rest.

When, on the contrary, the test diet shows a complete absence of tolerance, one must proceed much more cautiously. The next step is to test the urine for oxybutyric acid and its allies. If the test is positive (that is, if a few drops of perchloride of iron solution turn the urine a dark port wine color), the patient is always in danger of coma, and apparently this may be precipitated by a sudden change of diet. The carbohydrates are then to be reduced very gradually; and half an ounce to an ounce of sodium bicarbonate is to be administered in the twenty-four hours. In this way a sugar-free and proteid diet may be reached in safety, or the general condition may deteriorate and coma threaten. Under this latter condition it is best to abandon all attempts at a rigid diet and allow a definite amount daily of carbohydrates. For in these severe cases a proteid diet is as harmful in the direction of increasing the sugar in the blood as a carbohydrate one. Even when everything goes well, it is not advisable to exceed 500 grams of proteids per day; and if on this, sugar excretion does not diminish, or the patient loses weight, or coma threatens, a weighed quantity of carbohydrates should be added.

When the perchloride test is negative (showing the absence of oxybutyric acid and its congeners), a strict diet can be enforced without much anxiety, and suddenly or gradually, the latter preferably. Bacon, eggs, ham, all meats, fowl, and fish, sugar-free milk, tea, coffee, cocoa (if not adulterated with starch), saccharin, diabetic biscuits or rusks, diabetic bread, soups, cheese, salad with plenty of oil, thick cream, alcoholics in any sugar-free form, and green vegetables, may be allowed. If the diet agrees with the patient and under it sugar excretion ceases, it should be continued as long as possible, the tolerance being again tested after a few weeks, when frequently it will be found that a certain assimilating power has been gained. If this be the case a small amount of carbohydrate is permissible, the urine being carefully watched. More commonly, however, the loss of assimilating power is progressive, the patients passing into the group in which a sugar-free diet does not suffice to banish entirely the sugar from the urine.

Concerning particular articles of diet, it may be said that the real value of an article to the diabetic is measured by the amount of fat it contains, as fats form the one class of foods which cannot increase the urinary sugar. The best forms are butter, cream, and salad (olive) oil. On a strict diet, oysters and liver are to be excluded, as they contain glycogen; otherwise the patient has at his service the whole animal kingdom except milk. To the latter diabetics react very differently, some taking it well, while in others it increases the

glycosuria and thirst. There is probably too great a tendency to eschew potatoes, as they are not a very starchy food (containing only 20 per cent., while bread contains 50 per cent.), and, moreover, they serve as a good vehicle for fats. As regards vegetables, one may say, roughly speaking, that all portions growing above ground are allowable, while the underground portions are storehouses of starch. Fresh fruits are allowable with caution; dried fruits never. Greasy nuts are valuable on account of their fat. Some patients are able to assimilate lævulose, though all other sugars do harm. In any case its use is an experiment, and its price will operate to deter any free use of it.

Beverages must play a large rôle in the dietary, and no medical reason exists for restricting them. But all sweetened aerated beverages, sweet wines, and malt liquors must be excluded. Alcohol is an undoubted food for diabetics, it aids the digestion of fats, and should be given daily.

When coma is imminent, all attempts at rigid diet should be abandoned, as there is no doubt that the production of the acid products causing coma is facilitated by too much proteid consumption. Skimmed milk should be given freely, with sodium carbonate. Also alcohol should be given freely, as it limits the destruction of the proteids.

In elderly persons the disease has not the same tendency to progress, and, in the absence of complications, it usually suffices to stop the consumption of sugar and restrict that of starch. Many of these patients, especially the obese, improve under all-round restricted diet. Alcohol must here be used with much more caution, as, especially in the form of beer, it seems to be the cause of some case of glycosuria.

WHAT WE OWE TO EXPERIMENTS ON ANIMALS.

In June, 1893, Dr. W. W. Keen wrote, in *Harper's Magazine*, a powerful and well-considered article in defence of vivisection. He showed that to experiments on animals is due the majority of the great discoveries upon which surgery is based, and that without the knowledge gained thereby, operations which are now conducted to a successful issue, would have been impossible.

Dr. Stephen Paget has just published a pamphlet containing a short summary of the facts previously stated in his book, "Experiments on Animals." To attempt to recapitulate or to mention in detail the information contained in Dr. Paget's work would be futile, within the limits of an editorial, but it amply bears out, so far as physiology is concerned, the evidence of Darwin in 1878, who said: "I am fully convinced that physiology can progress only by the aid of experiments on living animals. I cannot think of any one step which has been made in physiology without that aid." Experiments on animals in the past have been the foundation of physiology, as well as the means of building its superstructure, and in the future will exercise a profound influence for good on medical and surgical treatment.

In the advance of our knowledge of pathology, bacteriology, and therapeutics, experiments on animals have been predominant factors. Paget gives numerous instances of the beneficial results to these branches of medical science and consequently to the human race, which have ensued from experiments on animals, and says in summarizing the amount of knowledge gained by these means: "As in physiology, so in pathology, many examples have been omitted for want of space. Nothing has been said of the treatment of myxœdema and sporadic cretinism with thyroid substance, or of the work of Magendie and Bernard on the selective action of drugs, or of other experiments in pharmacology, or of Calmette's and Fraser's work on snake-venom and antivenene, or of Hunter's recent work on pernicious anæmia. Nothing has been said of many excellent methods that we owe indirectly, but not directly, to experiments on animals: for instance, the uses of electricity in the diagnosis and treatment of injuries and diseases of the nerves and nerve centers. Let us leave all these present gains, and look into the near future. Take diphtheria, or take tetanus. All further knowledge of them, all better treatment of them, will come out of our present knowledge and our present treatment, which have come out of experiments on animals. Take cancer: It is possible that any research into this vast group of diseases should lead to practical results without the help of these experiments? Take rheumatic fever, or take ulcerative endocarditis. Can anybody doubt that the best hope of a better treatment of these diseases is in bacteriology? Everywhere, in every civilized country, the experts are hard at work in the unity of science. *Securus judicat orbis terrarum:* the whole world is of one mind here, and one faith."

The attitude of the antivivisectionist in the face of all the evidence in support of the value of experiments on animals is curious and not easy of explanation. The leaders of the movement are, for the most part, impelled by worthy motives. Cranks, of course, are to the front. Some of the prominent antivivisectionists are actuated by conscientious motives, others are propagandists who discern, in a matter which appeals so directly to the feelings of the community, an opportunity to advertise themselves. Some have a vague knowledge of physiology—they believe, however, as much as they wish to believe, and endeavor to attach to their own views the mass of the population. It is a case of the blind leading the blind. The majority of those who declare themselves opposed to experiments on animals are profoundly ignorant as to what these experiments consist of and the manner in which they have advanced and are advancing our knowledge of medical science. The popular idea of the vivisectionist is that he is a person of callous brutality, utterly without bowels of mercy, who mutilates and causes exquisite pain to living animals, not so much for the benefit of the human race as to gratify his savage instincts. It has been proved on several occasions; presumably with the view of exciting widespread indignation against the practice of vivisection, that the secretaries of antivivisection societies have disseminated misleading literature, and in many ways have not conducted their campaign in a fair and candid manner. The aim is to create a prejudice, and some of the methods adopted to do so are open to question. Medical men are handicapped in

that they, from the very nature of the circumstances, are unable to make the general public understand the true bearings of the matter. The ordinary individual knows nothing of physiology or of technical terms, and on account of this lack of knowledge, it makes it very difficult, almost impossible, for the medical man to convince him by argument. If the man in the street could be persuaded, first, that experiments on animals are conducted in as humane a way as possible, and that the animal experimented upon is spared acute suffering by means of anæsthetics; second, that the person engaged in experimental research is as tender-hearted, perhaps, as most people, and further that it is against his interests to cause undue pain to animals for the reason that the laws regulating these methods of investigation are very strict, and if brutality is exercised and found out, not only will the experimenter himself be put under the ban, but the entire system will be discriminated against, and, lastly that such experiments have been of incalculable benefit to the human race, then he would not be so ready to stigmatize "experiments on animals" in the wholesale manner as it is his general custom to do.

The latest report for England and Scotland on this matter to Government was printed on June 8, 1903.

By it was shown that six out of seven experiments are of the nature of inoculations. It is these, and these alone, that are made without anæsthetics. In a very large number of them there is no result and no possibility of pain. All the major operations are performed under anæsthesia. "The animals," says Paget, "may be compared with a number of like animals after operation, under anæsthesia, by a veterinary surgeon, with this difference, that many of them lose health, or suffer some disablement, and then die, or are killed. But whatever is done must be done under anæsthesia; nothing must be done, either at the time or afterward, that could cause pain without anæsthesia. Some of them might be compared to pet animals kept alive throughout the distress and infirmities of old age. Anyhow, they cannot be compared with a like number of sheep and cattle mutilated, without anæsthesia, by farmers and breeders; nor with a like number of pheasants and rabbits wounded, without anæsthesia, in sport."

Professor Huxley, who always spoke his mind to the point, whatever he betided, said some years ago, referring to experiments on animals: "If the alternative was actually put, and they had to choose between the sacrifice of a dog and the sacrifice of a man, which should it be? There was no choice. To save the dog in such a case would mean murder, and all who encouraged the act by word or deed would be accomplices. This was how the experimenters viewed the case, and, sad as the alternative was, they had no choice."

Professor Eliot declared that to interfere with or to retard the progress of medical discovery is an inhuman thing. Within fifteen years medical research has made rapid progress, almost exclusively through the use of the lower animals, and what such research has done for the diagnosis and treatment of diphtheria, it can probably do in time for tuberculosis, erysipelas, cerebrospinal meningitis, and cancer to name only four horrible scourges of mankind which are known to be of germ origin.

However, it would be idle to multiply instances in which experiments on animals have been the means of saving human life and of lessening human suffering. The position of modern surgery and the present-day treatment of diphtheria alone would justify the method. Medical men know all this, and are therefore able to appreciate vivisection, while the general public are ignorant and consequently have conceived a prejudice against it. Books like Stephen Paget's "Experiments on Animals" and "The Case against Antivivisection," epitomized and easily comprehensible by the lay reader, should serve a good purpose by diffusing a more intelligent knowledge of the matter among the community at large than exists at the present time.

Human and Bovine Tuberculosis.

Ever since the time that Professor Koch set the scientific world agog with his conversion to the theory that bovine tuberculosis was not communicable to man, discussion has ebbed and flowed with regard to the validity of his utterances. Some men have seemingly demonstrated by experiments that the distinguished German was wrong while others have concluded from investigations that he was right. American and British medical men have, as a rule, taken the view that Koch's opinions were not upheld by experience and that the weight of the evidence was against his theory. A British commission was formed some time ago to investigate the matter thoroughly, and has now published an interim report. It is stated that this report was issued because even at this stage of their researches, the members of the commission have become convinced that in the main points of his hypothesis Professor Koch was at fault.

The *British Medical Journal* of June 4 deals with the matter editorially, and says in part regarding the findings of the commission: "Of the twenty strains of human origin, seven gave rise at once in cattle to acute tuberculosis with widespread infection of lungs, spleen, liver, lymphatic glands, etc. In some instances the disease was of remarkable severity. The other strains, with two exceptions, produced a more or less localized lymphatic infection, with at most a very small amount of tubercle in the lungs and spleen. Tuberculous material, however, taken from the bovine animals thus affected, and introduced successively into other bovine animals, or into guinea-pigs, from which bovine animals were subsequently inoculated, has, in the case of five of these strains, ultimately given rise to general tuberculosis of an intense character. In the case of two strains the disease produced by the inoculation was limited to the spot into which the material was introduced. This occurred in two instances only at the very beginning of the inquiry. The disease thus set up in the bovine animal by material of human origin was compared with that set up in the bovine animal by material of bovine origin, and the commissioners report that the one, both in its broad general features and in its finer histological details, was identical with the other. They have failed to discover any character by which the one could be distinguished from the other, and state that their records contain accounts of the necropsies of bovine animals infected with tuberculous ma-

terial of bovine origin which might be used as typical descriptions of ordinary bovine tuberculosis." These conclusions are entirely contrary to the views expressed by Professor Koch, and as the *Lancet*, June 4, remarks, "Should prevent the framing or modifying of legislative measures in accordance with the view that human and bovine tubercle bacilli are specifically different from each other, and a wholly different thing from the disease caused by the other."

As to the menace to man occasioned by the consumption of tuberculous milk and meat, its measure cannot be estimated, perhaps neither of these agencies are the cause of tuberculosis in man and if so to no great extent. But as a result of the investigations which have taken place within the past few years with regard to the relations of bovine and human tuberculosis, and especially as a result of the researches of the British commission, both our milk and meat supply should be carefully inspected and strictly guarded.

A Philanthropic Endeavor to Reduce the Mortality among Infants in Chicago.

To save the lives of the children of Chicago's poor, the Milk Commission of the Children's Hospital Aid Society has begun its summer campaign. Through the work of the commission last year in supplying pure milk and educating mothers to give their babies proper diet during the hot months, the infantile death rate was reduced, and this year the work of this new philanthropy will be carried on with greater energy and upon a larger scale. The coming of Dr. Lorenz to Chicago first called public attention to the fact that comparatively little was being done for the sick and crippled children of Chicago. A public call sent out from the Chicago Woman's Club resulted in the organization of the Children's Hospital Aid Society, which was incorporated in January, 1903.

Distribution of 223,200 gallons of milk was the great work accomplished last summer between July and November, and this with only six persons paid for their services. When one considers that the milk is strained, filtered, Pasteurized, sealed in bottles, and distributed to thirty-five stations maintained throughout the city, and all within twelve hours from the time the milk is furnished by the Jersey herds in Wisconsin, it will be admitted that this systematic charity work presents features of organization more complete than evidenced in any other undertaking for the benefit of the city's poor in Chicago.

The milk is prepared in various modifications, the aim being to render it in all cases as near the strength of mother's milk as possible. Modification No. 1 is suited to young babies, with an increasing strength ratio up to the whole milk, suitable for older children, adult typhoid fever patients, or other invalids desiring and needing a fresh, pure, wholesome milk. The charges made for the modifications are all nominal and very low. Modification No. 1 sells, in a three-ounce bottle, sufficient for a single feeding of a young child, for one cent. No. 2 comes in a six-ounce bottle for two cents. No. 3 has a similar valuation. An eight-ounce bottle of No. 4 calls for a payment of three cents, and No. 5 costs the same.

The first work undertaken by the Children's Hospital Aid Society as a whole was a thorough investigation of Chicago's facilities for caring for sick and crippled children. It was found that out of the twenty-seven city hospitals visited children's wards were maintained in only eighteen; the total of three hundred and twenty beds thus furnished included the resources of the Home for Destitute Crippled Children. Only one Chicago hospital, the Maurice Porter, is devoted exclusively to children, and the only two places of refuge for children afflicted with infectious diseases may be found in the Memorial Institute, maintained in connection with the Presbyterian Hospital by Mr. and Mrs. Harold F. McCormick, and the City Smallpox Hospital at Dunning. Children suffering from infectious diseases must still be sent to Cook County Hospital or to the Dunning Infirmary unless eligible for one of the ten beds, exclusively retained for scarlet fever patients, of the Memorial Institute. The work of the Children's Hospital Aid Society during its first year and a half has resulted in greatly improved conditions, and in eleven hospitals at present maintaining no children's wards, the little ones are to be received shortly. Eight old-fashioned and not altogether perfect wards in other hospitals are to be rebuilt or replaced by the pavilion system.

Some time in the near future the society hopes that a special hospital for children, with long-needed improvements in the facilities for treatment of chronic child invalids, crippled and mentally defective children, and public school children in need of the eyeglasses their parents lack means to provide, may be brought into existence in Chicago. But for the present its efforts are generally directed to ameliorating prevailing conditions.

News of the Week.

Sanitary Work on the Isthmus.—T. C. Cunningham of New York, a member of the Canal Zone Police Department, died July 16, at Panama, from yellow fever. This was the first case of the disease known to have occurred in the zone since the arrival of Governor Davis. This year there have been fewer than ten cases of yellow fever on the isthmus. Col. William C. Gorgas, chief of the sanitary department, arrived at Colon four weeks ago and is working hard, with every promise of ultimate success, to improve health conditions in the Canal Zone. A requisition has been made for 100,000 yards of wire netting with which to screen the various buildings along the line of the canal, so as to protect the officials and employees from mosquitos. The work of sanitation now going on under the direction of Dr. Gorgas includes not only a general cleaning up of the towns and villages, but a systematic anti-mosquito crusade. Ponds and pools of standing water are being covered with kerosene, etc. Work has also begun on the drainage of swamps and mosquito-breeding places in the zone, which will require something like a year to complete.

Pneumonia Prevalent This Summer.—Dr. Darlington, Health Commissioner of New York, has asked of the Board of Estimate an appropriation of $10,000 to pay the expenses of a commission to study the causes, determine the nature, whether infectious or contagious, and devise means for the prevention of pneumonia, which has been strangely prevalent in the city during the present summer. The commissioner is quoted as saying, in explanation of his request for a commission, that "since the beginning of this summer the increase in the death rate from pneumonia has been alarming. In fact, since the summer began the number of deaths from this cause has been far greater than the number of deaths from the *General Slocum* disaster. It is a subject which demands the closest scrutiny and the best of scientific means for its checking."

The Second Congress of French-speaking Physicians of North America was held at Laval University, Quebec, on June 28-30, under the presidency of Dr. Foucher. The attendance was large, and was not confined to physicians speaking the French language, as many of the sister societies of Canada accepted

the invitation to send representatives to the congress. France sent an official delegate, Professor Pozzi.

Preliminary Requirements for Medical License Examination in Missouri.—The State Board of Health of Missouri, under date of July 5, issued the following circular: "Every applicant for license to practise in the State of Missouri shall present documentary evidence of having a university or college degree, or high-school diploma; in lieu thereof the applicant must pass a satisfactory examination before the State Superintendent of Public Instruction upon all branches embraced in a four years' high-school course. This is an absolute requirement, and no applicant will be allowed to enter the examination without having complied with this order."

College Appointments in Cincinnati.—Dr. Henry L. Woodward has been appointed assistant to the chair of Physiology in the Medical College of Ohio, medical department of the University of Cincinnati. Dr. Louis G. Heyn has been appointed assistant to the chair of Chemistry in Miami Medical College, Cincinnati.

Hospital Improvements in Philadelphia.—The German Hospital of Philadelphia is to be improved at a cost of $20,000 by the addition of a new dining-room and a dormitory over the kitchen, the fitting up of a new diet kitchen, and the introduction of new plumbing. The Presbyterian Hospital is to be enlarged by the erection of a four-story and basement brick maternity pavilion, seventy-three feet, seven and one-half inches by thirty, to contain a dining-room for the resident physicians, operating and instrument rooms, wards, kitchen, pantry, linen room, and dormitories.

The Death Rate in Chicago.—For the first six months of this year, according to the weekly bulletin of the Chicago Department of Health, the total deaths, 14,131, were 1,070 fewer than during the corresponding period of 1903, and the death rate, 14.69 per 1,000, was 10.9 per cent. less. There were 379 fewer deaths under five years of age—a reduction of 10 per cent.; but this decrease was entirely among those of the milk-feeding period. Of these, there were 1,014 deaths, as compared with 1,660 last year, a decrease of 646 deaths, or nearly 40 per cent. The quality of the milk supply and the rarity of contagious disease account for this marked reduction. There was a 6.4 per cent. increase of the deaths among the aged, those over sixty years old. Only five of the important causes of death show increases, namely: Apoplexy, 93; Bright's disease, 106; consumption, 113; cancer, 42; and violence, other than suicide, 58. The following showed the decreases indicated: Acute intestinal, 27; bronchitis, 134; convulsions, 30; diphtheria, 89; heart disease, 14; influenza, 63; measles, 221; nervous diseases, 171; pneumonia, 50; scarlet fever, 111; smallpox, 39; suicide, 52; typhoid fever, 107; whooping-cough, 187.

Chicago Milk.—During a period of about two months covered by his reports to the Civic Federation, Professor Jordan, of the Bacteriological Department of the University of Chicago, found that about 31 per cent. of the 291 samples of milk examined by him were below the city standard in respect of total solids. During the same period the findings of the Municipal Laboratory indicated a quality of milk just about four times as good. The Chicago *Tribune*, in commenting on the milk question, says: "Were the city inspectors four times as fortunate in the samples of milk which they happened to collect? Was Professor Jordan four times as rigid in the use of alkaline tablets, nutrient gelatins, and Quevenne lactometers? Or does the habit still survive among the city inspectors of taking a pleasant little morning drive in their municipal buggies along the boulevards, and of incidentally picking up a few samples of the superior kind of milk which is served to boulevard customers? Whichever of these questions may touch the right spot, it remains true that a discrepancy exists which, out of regard for the health of Chicago, ought to be explained. Is our milk as rich as the city inspectors think, or is it as thin as Professor Jordan's laboratory indicates? And, further, should not the city, as soon as it can afford to do so, provide for an inspection of milk not only with regard to its percentage of total solids, thereby establishing its nutritive value, but also with regard to its bacterial inhabitants, to prevent the spread of disease through milk?" Bacteriological tests of milk are made as regularly as possible, with a small staff of inspectors and bacteriologists, according to Health Commissioner Reynolds, who thinks the Health Sanitation Committee of the Civic Federation, in its recent criticism above mentioned, should have taken into account the small appropriation for inspection. The committee secured tests of 291 samples in two months, and found many of them below grade with regard to butter fat and solids. That four times as much milk escapes supervision as is tested is considered an exaggeration when based on the investigation of 291 samples, but Dr. Reynolds considers that some milk is bound to escape the inspectors because of the small staff of men given him to work in conjunction with the City Laboratory.

Pure Milk Fight in Cincinnati.—The Board of Health has ordered the vacation of two dairies in Cincinnati within sixty days. Several stables were ordered whitewashed and cleaned and others must have the roof raised.

The Children's Hospital Aid Society of Chicago.—The officers and directors of this society, the aims and accomplishments of which are described elsewhere in this issue, are: *President*, Dr. Frank Billings; *Vice-President*, Mrs. Geo. W. Plummer; *Secretary*, Mrs. Harold F. McCormick; *Treasurer*, Mr. E. T. Keith; *Directors*, Drs. John Ridlon and W. S. Christopher, Judge O. N. Carter, Mrs. W. P. Henneberry, and Mr. Medill McCormick. The *Milk Commission* is headed by E. P. Bicknell of the Chicago Bureau of Charities, with Mrs. George M. Moulton as managing director, and Dr. Frank Billings, Miss Fulmer, Dr. Isaac A. Abt, Mrs. Geo. W. Plummer, and Mr. Medill McCormick to complete the committee.

Enlarged List of Notifiable Diseases in Philadelphia.—In accordance with a resolution adopted by the Philadelphia Board of Health the list of notifiable diseases has been enlarged so as to include the following: Cholera, yellow fever, malarial fever, typhoid fever, typhus fever, scarlet fever, smallpox chickenpox, diphtheria, diphtheritic croup, cerebrospinal meningitis, measles, rubella, whooping-cough, tuberculosis, pneumonia, erysipelas, puerperal fever, plague, trachoma, leprosy, tetanus, glanders, hydrophobia, and anthrax. The penalty for failure to make report of such diseases is a fine of from $5 to $50 or imprisonment for sixty days. Practitioners of veterinary medicine are required to report cases of glanders, anthrax, tuberculosis, tetanus, and rabies in animals or man.

The St. Louis Society for the Prevention of Tuberculosis held a meeting on July 9, and formulated plans for permanent organization and active prosecution of the work. Dr. William Porter is vice-

president of the society and a number of representative citizens spoke in favor of the plan. Among the speakers was Miss Lillian Brandt, statistician of the United Charities of New York City, who spoke of the work in that city. Miss Brandt said that the Health Department requires reports on all cases of tuberculosis from the institutions and physicians under whose care the cases may come. These reports contain the names and addresses of the patients and the particulars of the cases. Inspectors make rigid investigations, and the Health Department, in a few extreme cases, has exercised the right to remove patients and place them in quarantine. Dr. John H. Simon, health commissioner of St. Louis, read some statistics on tuberculosis and said that over 10 per cent. of the deaths in St. Louis last year were due to tuberculosis, while the records of 1860 showed the percentage was only 8. Dr. C. A. Snodgrass, city bacteriologist, spoke of the dangers of the spread of the disease from street cars and other public places, and said the best way to prevent the spread is to educate the people in the nature of the disease. The society will use every effort to secure legislation similar to that in force in New York. A number of committees were appointed, the members of the medical committee being Drs. Wm. Porter, chairman; H. Wheeler Bond, J. W. Harris, Geo. Homan, C. H. Hughes, H. W. Lyman, W. A. McCandless, W. G. Moore, Jesse S. Myer, E. W. Saunders, J. H. Simon, Jos. Spiegelhalter, Justin Steer, J. H. Tanquery, Geo. M. Tuttle. The organization has been linked with the Civic Improvement League, and all of the leading charity organizations are represented

The "Colorado Medical Journal" recently issued a special number on tuberculosis, and made the announcement that, with that number, it would inaugurate a new policy of devoting much more attention to the subjects of climatology and tuberculosis. In this way, without becoming exclusively a journal of climatology and tuberculosis, it would, in a great measure, fill the vacancy caused by the suspension, not long since, of the *Journal of Tuberculosis*.

Public Instruction in Tuberculosis.—The Illinois State Board of Health recently issued a pamphlet written especially for the laity, and intended for distribution broadcast, in which consumption is described, its ravages clearly pointed out, and rules for its prevention and limitation of its spread detailed. The State Board of Health announces that it will make free examination of sputa in needy cases.

Appointments at St. Mary's Hospital, Chicago.—Dr. Alfred C. Croftan has been appointed physician-in-chief, and Dr. A. J. Ochsner surgeon-in-chief, to St. Mary's Hospital, Chicago.

The Beth Israel Training School for Nurses.—The graduation exercises of this school were held on Tuesday evening, July 12. Addresses were made by Dr. L. J. Ladinski and Mr. Edward Lauterbach. The diplomas were given by Mr. Joseph H. Cohen, President of the Beth Israel Hospital. A class of eleven was graduated, the valedictory address being delivered by Miss Lena Rabinowitz.

The Product of Cod-liver Oil in Norway up to May 28 of the present year has been more than five times what it was for the same period of 1903, according to a recent report of United States Consul Cunningham, at Bergen, made to the Department of Commerce and Labor. As a result of this increase, the price of the commodity has been gradually declining, and the sales have not been very great. There are over 3,500 boats engaged in the fisheries in Finmarken, where the season has been exceedingly favorable. The output last year was almost *nil*.

Increased Death Rate for Philadelphia.—There were reported to the Philadelphia Bureau of Health 483 deaths for the week ended July 16, an increase of 39 over the preceding week. The heat is responsible for a large number of deaths among children, 84 deaths being due to diarrhœa and enteritis in children under the age of two years. Sixty-four deaths were due to pulmonary tuberculosis. The number of cases of typhoid fever was 58, with 10 deaths, as compared with 56 cases and 7 deaths for the preceding week. There was but one case of smallpox, while there were 36 of scarlet fever and 35 of diphtheria.

Women and Medicine.—Prof. T. Clifford Albutt presented the prizes, on June 23, at the London School of Medicine for Women, Hunter Street. In the course of his address he remarked that the lady doctor had come to stay, and there was now no reason for defending a school of that kind. Women had been wise in having a school to themselves, but the time had now come when they must take a step forward and be members of the great colleges and guilds of their profession. He would be glad to see women belonging to the College of Physicians and the College of Surgeons, and it was an undoubted fact that at the Congress of Physicians men had derived great interest and instruction from papers read by women.—*The Medical Press and Circular.*

Obstructing Medical Union in New York State.—The proposed consolidation of the New York State Medical Association and the Medical Society of the State of New York is opposed by the Onondaga County Medical Association. Willard A. Glenn of Syracuse appeared before Justice Fitzgerald on Wednesday in opposition to a motion for an order compelling the association to consent to union. The lawyer of the association said that there was no actual opposition to consolidation, but that his clients believed that the merger should be carried out in accordance with the terms of the General Corporations law, by which each association would be wound up prior to the establishment of the new organization. The result of this would, of course, be that the Medical Society of the State of New York would cease to exist, a catastrophe which its members would never permit to happen. Any opposition to the present plan of consolidation amounts practically therefore to opposition to medical union in the State.

New Home for Nurses.—The Jewish Hospital, Cincinnati, has applied for a permit to erect a new nurses' home in Burnet Avenue. The structure is to be a three-story brick building and will cost $10,000.

American Electro-therapeutic Association.—The fourteenth annual meeting of this association will be held at the Inside Inn, St. Louis, Mo., September 13, 14, 15, and 16, 1904. The scientific sessions will be held only in the mornings, leaving the afternoons free in which to visit the attractions of the fair. It is believed that a large proportion of the members of the association will be present this year, as the World's Fair offers many attractions in itself; and in addition to the convention of the association, there will also be held in St. Louis, from the 8th to the 15th of September, the annual convention of the American Röntgen Ray Society and the International Electrical Congress.

Cholera in Persia.—A despatch from Baku states that refugees are arriving there from Teheran and tell terrible stories of the ravages of cholera. They

say that on some days the mortality has reached nine hundred. The Europeans are abandoning their property and are fleeing to a camp in the mountains. The quarantine stations are almost without food. The Russian Government has ordered the closing of the frontier for the purpose of preventing the introduction of the disease into the southern provinces.

Obituary Notes.—Dr. David J. Fitzgerald, one f the leading physicians of Northern New York, died at Glens Falls, N. Y., on July 17, of apoplexy. He was born in Ireland forty-six years ago, came to this country when young, was graduated from the Fort Edward Collegiate Institute in 1876, and the Albany Medical College in 1884. After a course in the New York Post-Graduate School he located at Glens Falls in 1886. A widow and two daughters survive. One of his brothers is Dr. John F. Fitzgerald of the Public Charities Department in Brooklyn and Queens.

Dr. Frank Anthony Walke died July 12 at his home in Norfolk, Va., aged seventy-three years. He was a graduate of the Medical Department of the University of Pennsylvania in the class of 1852, and served in the medical corps of the U. S. Navy. During the Civil War he was active in the naval medical service of the Confederacy.

Dr. A. J. Atkinson died at Lewistown, Pa., on July 12, at the age of eighty-three. He was a surgeon in the U. S. Army during the Civil War.

Dr. Eli J. Zook died at Newville, Pa., on July 9, at the age of sixty years. He was graduated from Jefferson Medical College in the class of 1878.

Dr. Willard P. Derickson died at Wilmington, Del., on July 10, as a result of spinal meningitis. He was graduated from Jefferson Medical College in the class of 1891.

Obituary.

EDWARD W. LAMBERT, M.D.,

NEW YORK.

Dr. Edward W. Lambert died at his home in this city on Sunday, July 17, of disease of the heart. He had been seriously ill only about a week. He was born in Boston, Mass., on February 15, 1831, and was graduated in arts from Yale College in the class of 1854, just missing the celebrated '53, with most of the members of which, however, he was intimately acquainted. The same year he entered the College of Physicians and Surgeons of this city and received his degree from that institution in 1857. For two years after that he served on the house staff of Bellevue Hospital, and in 1859 entered upon the practice of his profession.

Dr. Lambert was one of the pioneers in medical insurance work. He early became associated with Henry B. Hyde who, in 1859, founded the Equitable Life Assurance Society, and he was made the society's first medical director. During the period of forty-five years since then he has remained chief of the Equitable's medical staff, although of late his duties have been rather those of consulting medical director.

Dr. Lambert was one of the last of the "old guard," at one time an assistant of Willard Parker and a contemporary of Draper, Sands, and Markoe. He was a member of the New York Academy of Medicine, the Pathological Society, the Medical Society of the County of New York, the Medical and Surgical Society, the Society for the Relief of Widows and Orphans of Medical Men, the Century, University, and Yale Clubs, and the New England Society. Of his four sons, three, Adrian V. S., Alexander A., and Samuel W., are physicians practising in New York.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

MR. CHAMBERLAIN ON TROPICAL MEDICINE—CONSUMPTION AND SANATORIA—HYDATID DISEASE OF PELVIS AND ABDOMEN—CHARITY MEETINGS—THE KING'S FUND—STREET AMBULANCES—LORD ALVERSTONE TO STUDENTS—A STEREO-PHOTO ANATOMICAL ATLAS.

London, July 1, 1904.

The Royal Institute of Public Health last night gave a banquet in recognition of Mr. Chamberlain's services to Tropical and Preventive Medicine. About two hundred members of the institute and a number of distinguished guests were present. The Honorary Fellowship of the institute was presented amid much enthusiasm to Mr. Chamberlain, Lord Iveagh, and Mr. Balfour. The president (Prof. W. R. Smith), in proposing "our guest," said the ex-Colonial Secretary had done more than any one who had held that office to promote the health of our countrymen in Greater Britain. Fortunately in this country we could put aside political armor and meet to do honor to a great Englishman.

Mr. Chamberlain, in acknowledging the toast, said that as secretary for the colonies he had had brought home to him how important was care for the health of those doing our work beyond the seas, and taking advantage of the opportunities of office he was able to secure some expression of the interest universally felt in such an institution as the one he was addressing. He had often heard it said that while surgery had made gigantic progress in this generation, medicine had not advanced in due proportion. Well, to borrow an expression from the Prime Minister, he could say, "I am a child in these matters." He only knew that in the last few years medical research, aided by surgery, had thrown a flood of light on the origin of the disease, and that was a step toward its cure. While all looked with confidence on curative medicine, all agreed that preventive medicine was better still. Without sanitary reform social reform was an empty phrase. The housing of the poor, the attempt to prevent the deterioration of the race, and other things to which legislators devoted such of their time and attention as they could spare from party conflicts—all such things were founded on sanitary reform. Preventible disease was the great agent filling our workhouses, raising our taxes, weakening the fiber of the people, preventing us from competing successfully in that eternal struggle for existence which must go on as long as the world lasts. It was to the efforts of such men as Sir Patrick Manson, Major Ronald Ross, and Professor Haffkine that his attention had been chiefly directed. With all the investigations going on, he believed—sanguine optimist as he always was—they would in time make those tropical countries, each of which in turn had been called "the white man's grave," places where white men could live in comfort.

A new convalescent Home for Consumptives in connection with the Brompton Hospital was opened on the 25th ult. by the Prince and Princess of Wales. It is, situated at Camberley, about thirty miles from London, 400 feet above the sea level, in grounds of about twenty acres in extent. The soil is gravel and sand. Pine woods give some shelter from the winds, except on the south side. The total cost is said to be £70,000, and it will require an expenditure of £10,000 a year to keep it going. The Prince expressed the pleasure of himself and the Princess in assisting in the inauguration of the sanatorium, and hoped their presence might be considered as evidence of a desire to preserve the connection of their family with the Brompton Hospital ever since the foundation stone of the original building was laid by his grandfather, the Prince Consort, sixty years ago. He also referred to the King's Sanatorium for Consumptives now in course of erection.

This question of preventing consumption—as well as of treating it—seems to meet us at every turn. There are some who say the whole subject has been too much boomed in one direction, though others are disposed to push it still further with the public. The Charity Organization Society, which likes to get a finger in every pie, had a meeting on Wednesday afternoon, at which both Sir D. Powell and Sir W. Broadbent blessed the work it had done in this matter. Sir Douglas insisted on the importance of the disease being recognized at the earliest stage and said there was no need to be hopeless. The disease had been steadily declining for the last fifty years and more rapidly during the last decade. The scheme of the C. O. S. was described at the meeting as concerned only with the very poor, and as directed to ensure such a stay in a sanatorium, and to free them from anxiety as to their dependents and afterward secure

suitable light employment for those who recover sufficiently to undertake it. An endeavor is being made to enable the society to pay for ten beds in a sanatorium.

The first annual meeting of supporters of a sanatorium at Davos named after the Queen was held here yesterday. The old Home for British Invalids at Davos, taken over by the "Queen Alexandria" Association, is inadequate and compares badly with the institutions of other countries; so a year ago it was determined to build—something not extravagant but worthy of the Queen's name. A recent entertainment at His Majesty's Theater produced £5 000 toward this object. The main object of the association is to cater for people unable to incur the whole cost of their treatment and who are only in the early stage of consumption.

Hydatid disease in the pelvis and abdomen was discussed at a late meeting of the Obstetrical Society when two rare cases were brought forward. The first, by Dr. Eden, was primary hydatid of the fallopian tube in a woman of forty, married thirteen years, never pregnant. A pelvic tumor was found and thought to be a dermoid cyst of the right ovary. Operated on in September, 1903, it turned out to be the distended, densely adherent fallopian tube filled with detached hydatid vesicles. No trace of hydatids elsewhere. The case is almost unique. Dr. Eden had met with but one other recorded case—that of Doléris in 1896—and he only knew of one recorded case of primary hydatid disease of the ovary, that of Pean, 1895. Pelvic hydatids usually begin in the peritoneum or connective tissue. The other case is very remarkable and was the subject of a paper by Dr. Cullingworth and Mr. Clutton, the patient having been under their joint care for about eight years. She was first examined by them in 1896 when twenty-four years old, when a rounded, fixed, fluctuating swelling in the suprapubic region was supposed to be a cyst of ovary or broad ligament. On operation hydatid cysts of both ovaries and right broad ligament, as well as of the omentum, mesentery, and abdominal wall were found. Moreover, a larger cyst was also present in the right loin and another below the sternum. The cysts of the ovary and broad ligament and as many as possible of the omentum were removed, the operation lasting two and a half hours. The patient's condition toward the end was extremely alarming. Three months later an incision was made above the umbilicus in order to deal with the other cysts. This revealed three large and several small ones attached to the liver. All but two were removed entire; the ectocystic walls of the two largest were reduced in size and attached to the incision. The shock was extreme. Another large cyst fell toward the spleen and was left for future operation. In November of the same year a large cyst in the left iliac fossa was evacuated, and a week later a suppurating cyst discharged its contents per rectum. Between this time and December, 1903, the patient submitted to eight operations, the longest interval between being two years.

Dr. Malins (president) hardly knew which to admire most, the persistence of the surgeons or the fortitude and endurance of the patient. Mr. Clutton remarked that the present satisfactory state of the patient was due to the fact, contrary to the usual experience, that the cysts had been limited to the abdomen. Had they invaded the thorax or brain, as so often happened, the result would have been different. Mr. Bland-Sutton suggested re-examination of the specimens to determine whether the colony really arose in the ovary or in the connective tissue of the broad ligament. In the majority of cases the parasite began in the subserous tissue. The number of cysts depended on the number of ova swallowed. The cysts and colonies gave rise to symptoms according to their rate of growth. Broad-cysts may be sown in the connective tissue of operative wounds, and so cysts often appear in the cicatrices.

A colonial list of birthday honors was issued after the home list. Dr. M. St. John Franks Kendal, M.B., C.B., of the Transvaal receives knighthood.

The Queen has promised to visit the East London Horticultural Show on the 14th, the proceeds of which are to be devoted to the London Hospital.

Princess Christian attended a meeting of the National Health Society on Tuesday at the Mansion House. Lord Derby said the society is doing good work in various parts of the country by instructing poor people on the means of preserving health. A modest training is given and certificates awarded to health visitors and sanitary inspectors. Lectures are also given under the auspices of the County Councils. The society is much indebted to the Princess for the interest Her Royal Highness has always displayed in this work.

The Duchess of Albany opened the three days' bazaar which closed last evening on behalf of the Royal Hospital for Incurables which was founded by Dr. Reed fifty years ago and has been under royal patronage all the time. At present it shelters 208 patients and gives pensions of £20 a year each to 700 others. Patients who can work contribute various articles, as do their friends, to this annual sale.

Lord Iveagh has sent the first instalment of an additional annual subscription of £500 to King Edward's Hospital Fund. When the fund was started in 1897 his Lordship gave £12,500 as a capitalized subscription. Donations of above $11,000 have been made toward the £9 332 per annum required to take advantage of a conditional offer.

A deputation of gentlemen interested in the provision of street ambulances waited on the city police authorities on Wednesday. Sir Wm. Church, Sir D. Duckworth, Sir Cooper Perry, Mr. Golding Bird, Mr. A. Bowlby, Dr. Arthur James, Secretary of Street Ambulance Association; Surgeon-General Sir Joseph Fayrer, and Surgeon-General Sir W. Hooper took part with others. The need for horsed ambulances and skilled attendants, in order that injured persons might be quickly taken to hospital with as little pain as possible, was urged by the speakers, who pointed out also how far we lag behind the United States in this matter. Sir Joseph Fayrer said he was ashamed that the chief city of the Empire should occupy its present position in this respect. The chairman (Alderman Alliston) promised careful consideration of the information submitted by the deputation and expressed a wish for a written report on the subject.

Lord Alverstone distributed the prizes at St. Mary's Hospital on Wednesday and gave the students some timely advice. He was delighted that the school kept in the front rank in athletics, but begged them to remember that these exercises are not the object of life but only a means of fitting them to do their serious work. In no other profession were gentlemanly feeling, high bearing, and honorable principles more essential. Moreover, no other calling offered greater opportunities for helping others. He would not have doctors turn preachers, but he felt that they must meet with many opportunities in their work of speaking words which were good for those in trouble.

A novelty in anatomical teaching: Messrs. Jack announce the forthcoming issue of "The Edinburgh Stereoscopic Atlas of Anatomy," to consist of 250 stereoscopic photos, in parts of fifty each, edited by Dr. David Waterston. The first section will be ready in the coming autumn, and it is hoped to complete the work early in 1905. The advantage of the stereoscope is obvious, and the position and relations of the various structures must be in this way accurately defined.

OUR PARIS LETTER.

(From Our Special Correspondent.)

N-RAYS—PHYSIOLOGICAL ACTION OF RADIUM RAYS—INTRAVESICAL SEPARATION OF URINE—CANCER OF THE STOMACH TREATED BY RÖNTGEN RAYS—EARLY DIAGNOSIS IN GLAND AND PULMONARY TUBERCULOSIS—SURGICAL TREATMENT IN ULCER OF THE STOMACH—PROSTATECTOMY—LACERATION OF THE COMMON CAROTID—GENERAL TUBERCULOSIS AN ECONOMIC PERIL—HEPATIC ORIGIN OF HEMORRHOIDS—EFFECT OF RADIUM ON THE BLOOD IN LEUKÆMIA—DEATH OF GILLES DE LA TOURETTE.

PARIS, June 15, 1904.

At the Académie des Sciences nearly all the meetings of late have been occupied with discussions on the *n*-rays, recently discovered by Professor Blondlot and Professor Charpentier of the faculty of Nancy. It is claimed that Charpentier has discovered that living beings, especially the muscles and nervous centers, give out special rays, called *n*-rays. These *n*-rays, as yet but little known, entirely distinct from *x*-rays, have been studied in a series of experiments.

Professor Bouchard, collaborating with Curie, has also studied the physiological action of the emanations of radium. By a special arrangement these authors have had mice and guinea-pigs kept in an enclosed place and forced to breathe air charged with radium rays. The animals first suffered from dyspnœa, then went into coma, became cold, and died. The investigators further ascertained that the tissues of the animals succumbing to the action of the radium are themselves radioactive. They have observed, on the other hand, that the injection of gas charged with the emanations of radium into the peritoneal cavity of guinea-pigs or rabbits, has no toxic effect.

At the meeting of the Académie de Médecine on June 14, an important communication was made by Tuffier and Mauté concerning the value of the intravesical separation of the urine of the two kidneys, with a view to the diagnosis of their functional and anatomical condition. The method used was that of Luys. They showed that this method makes it possible for one to know the exact

functional condition of one kidney in comparison with that of the other. They added, however, that the examination of the separated urines should be preceded by the examination, during several successive days, of the renal function as a whole, that is, of the 24-hour urine, and that it is only in view of such knowledge that one can learn from examination of the separated urines what part is taken by each kidney. The separation of the urines should be continued with the separator of Luys for about half an hour, or until 10 c.c. at least has been obtained from each kidney. In each of the separated products it is primarily important to know the relation between the freezing point and the volume excreted; that is, Δ V, which gives the number of molecules of solids excreted by each kidney in a unit of time. But the fact that the functional activity is notably diminished on one side is not necessarily diagnostic of a renal lesion on this side, for a simple obstruction in the renal circulation, as that produced, for instance, by a pararenal tumor, is sufficient to produce important modifications in the renal secretion.

Doumer and Lemoine of Lille have treated twenty cases of cancer of the stomach with Röntgen rays. They have obtained three definite cures, and in two other cases there was marked improvement. In all these cases the diagnosis rested on clinical symptoms, namely, tumor in the region of the stomach, gastrorrhagia, gastric pain, dyspepsia, and emaciation. In the favorable cases, not only did the functional symptoms disappear, but the tumor itself diminished or disappeared.

Professor Grancher has emphasized the value of making early diagnosis in gland or pulmonary tuberculosis, among the children of primary schools, for if this disease can be treated early, there will be a chance of saving a large proportion of the children. It is indeed well proved that the earlier treatment is begun, the more amenable to it is tuberculosis. To illustrate the need of treatment—in a boys' school 14 per cent. were found to have tuberculous lesions, and in a girls' school, 17 per cent. Professor Grancher thinks that schools for these children should be built in the country, where life in the open air, judiciously combined with studies, would cure the greater part.

In the Société de Chirurgie, Ricard, who has had more than one hundred cases of operative treatment of ulcer of the stomach, stated that it is not best to operate on ulcers of the stomach during the period of active hemorrhage, because such interference is useless and dangerous, and, moreover, that it is not best to operate on ulcers of the stomach unless they are complicated by hemorrhage or stenosis. In the latter case, the operation of choice is gastroenterostomy.

Pousson of Bordeaux discussed and defined the indications for prostatectomy. In twenty-three prostatectomies, he operated twenty-one times by the perineal route and twice by the transvesical. The first method gave a mortality of 19 per cent. and the second of 50 per cent. Pousson, in view of these figures, considers prostatectomy a serious operation. In his opinion, the indications for it are—difficulty in catheterization, vesical infection, at least when this is accompanied by pyleonephritis, and the coexistence of a vesical calculus. He much prefers the perineal route to the transvesical, because of the better drainage.

Lejars reported an interesting observation of Launay, who, in the course of extirpating a cancerous tumor of the thyroid, in a woman sixty-five years old, lacerated the common carotid for a distance of one and a half centimeters. Stopping the hemorrhage temporarily with artery clamps, Launay first removed the tumor, then proceeded immediately to suture the wound of the artery. This was done with a fine needle, by continuous suture. The operation succeeded perfectly, convalescence proceeded without incident, and the patient was presented three weeks afterward, completely cured, at the Société de Chirurgie. Seven months later, the patient continued to enjoy excellent health, and no cerebral trouble had appeared.

At the Société des Internes des Hôpitaux de Paris, Professor Grancher gave an address on general tuberculosis, considered as an economic peril. He described it as a terrible enemy, more difficult to vanquish than the great contagious diseases, as, for example, cholera. Against these, indeed, the government appoints an official armed with dictatorial power, who, supported by public opinion, completely sacrifices individual liberty to public health. He burns all objects which are sources of infection, and rigorously isolates all contaminated persons. A war undertaken in this way against tuberculosis is impossible, since this disease has penetrated almost every family and it would be necessary to arm one-half of France against the other half, instituting thus a veritable civil war. Since this method is impossible, it is necessary to find another less stringent, and to avoid difficulty by going to the source of the evil. For, as tuberculosis in the beginning is easy to cure, that is, when it exists as scattered tubercles which can be absorbed, so, on the other hand, when the lesions are advanced, when cavities are formed, therapy is in vain. Professor Grancher considered it above all important that the physicians who heard him should understand their duty of taking part in the grand struggle undertaken against tuberculosis. The chief duty of the physician, according to his idea, is to search out tuberculosis in its beginning, and thus to make early diagnosis, for at the time when the disease takes root, it is curable by rest, air, and forced feeding, in the enormous proportion of 80 per cent. To diagnose tuberculosis before the first stage is passed, in such a way as to save many human lives, and to aid in diminishing this terrible disease, is the primary duty of the physician. This early diagnosis can be made chiefly by auscultation, for the trained ear can easily detect at the beginning slight changes in breath sounds, and so make possible a correct diagnosis. It is thus by means of prophylaxis that the physician will be able to play his part, surely a great economic rôle, in the battle against tuberculosis.

In the Société de Biologie, Gilbert and Lereboulet gave an interesting report on the hepatic origin of hemorrhoids. Passive congestion of the portal system, due to hepatic alteration, is the chief cause, local causes being always secondary. It is true that most of the affections of the liver are accompanied by hemorrhoids, but this is because they induce portal hyperdistension, which, in turn, leads to dilatation of the hemorrhoidal veins. Hemorrhoids have often a considerable diagnostic value, since they may be the first sign of a latent affection of the liver, and treatment directed against that and against the resulting portal congestion, furnishes, by its success, a new proof of their hepatic origin. Direct massage of the liver, by modifying the hepatic circulation, may have an indisputably curative action on hemorrhoids.

Aubertin and Baujeard have recently studied the modifications of leukæmic blood under the influence of radiotherapy. In myelogenous leukæmia, radiography of the splenic region causes a diminution in the number of leucocytes, but this diminution is not regularly progressive. Each treatment, indeed, is followed by a sudden and considerable increase in the total number of white cells.

Among the deaths which have occurred recently in the scientific world we would mention that of Gilles de la Tourette, who was one of the brilliant pupils of Charcot. He was physician in chief of the Paris Exposition. He leaves works of real value, such as his books on the neurasthenic states, hypnotism, hysteria, and on nutrition and medication in nerve diseases.

EXECUTION BY ELECTRICITY.

To the Editor of the Medical Record:

Sir: In the Medical Record of June 25, 1904, is chronicled another instance of failure in electrocution. It occurred in the Ohio Penitentiary, where Michael Shiller received a shock of 1750 volts, and recovered. Later the condemned man was given 1900 volts without fatal effect. Still later another shock proved inadequate. Last month (May 25, 1904) Antonio Triala, an Italian, who killed a vaudeville singer, was sent to the chair. A shock of 1700 volts was given and continued for thirty seconds. Four more were required at intervals before Triala was pronounced dead. At the time it was explained that five shocks were necessary because the criminal was very thin and his body was a bad conductor, and also because his hair was thick and oily. A number of cases like those of Schiller and Triala might be recited. These suggest, at least to the mind of the writer, the question, are we ever entirely sure that the person in the chair is killed by the electric fluid? There are those who think that the so-called *post-mortem* is in most cases *ante-mortem*, and that the knife, not the electric current, does the work. Now if death is in reality occasioned by the so-called autopsy, it is hard to see how we have improved upon the medieval methods of depriving men of life judicially. Is vivisection any advance upon the old-time evisceration, empalement, crucifixion, and burning at the stake? I cannot resist the belief that in a large number of cases the criminal is killed, not by electricity, but by the surgeons who are the real executioners. That opinion is not mine alone, I share it with others in the medical profession and in other professions. There rests upon the table before me at this writing a letter which I received a few days ago from a prominent physician in New York City who has given much time to the study of electrical therapeutics. He frankly writes that he has long been of the opinion that a considerable number of those who have been sent to the chair could have been resuscitated after they had been pronounced dead, and up to the time of the so-called autopsy.

Will you allow me sufficient space in the Medical Record to suggest the propriety of returning to a classic method of inflicting the death-penalty which seems to

he writer much better than that now legal and practised in the State of New York. It is both humane and effective, as well as inexpensive. Centuries ago Socrates drank the fatal cup. Plato has preserved for us, in his Dialogues, a wonderful picture of the last hours of that great and good man.

We would not, as in the olden time, administer hemlock but there are many substances now known to physicians and chemists that give no pain, are inexpensive, and work much more rapidly than did the potion given by the executioner to the unfortunate philosopher. Chloroform might not be a bad substitute for electricity. Prussic acid is one of a number of chemical agents worth considering in this connection. There are narcotics that might be used. The criminal could be made to sink through a quiet sleep into that deeper sleep from which he will not revive as did the prisoner in the Ohio Penitentiary. Should he refuse the draught, a hypodermic injection would certainly cover the case.

It is contended by the advocates of electrocution that death by the current is painless. There is abundant reason for believing the contrary to be the case. A number of persons who have received shocks of high voltage from which they have recovered testify to the great distress they endured. The pain is described as having been intense. The following paragraph is taken from a communication addressed to the *American Inventor* by Mr. A. B. Brooks, an electrician of some celebrity. He accidentally got hold of a telephone wire grounded. He says: "The duration of the shock could not have been more than a couple of seconds. A man riding by on a wheel going at a good speed had only time to pass about thirty yards beyond me when the operator got through talking and opened the switch, yet I could see every spoke in the bicycle, and it barely seemed to me to be turning. I could feel every reversal of the current, and these reversals occur at the rate of sixty complete cycles per second It is this intense activity of the brain to electrical impressions that makes an instant of electrical shock seem hours to the sufferer Of course it is impossible to know what a man dying of strangulation suffers, but I will positively affirm that any man who has ever had a severe shock will prefer anything to another. The fact that my own case was not fatal does not alter my opinion that death by the electric chair is most painful. The sensations of pain and the elongation of the sense of consciousness of time seem to increase in direct proportion to the violence of the shock. If I suffered what seemed to me hours with a current which did not kill, what may not a man suffer with a stronger shock between the time of its first application and his final loss of consciousness."

May I also add that we want a court of pardons to relieve the executive from the responsibility of last resort, and we also want an official executioner who is educated for his work, and who will not be guilty of any of the miserable failures that so often occur The execution itself should have, as has been pointed out by another, these four prerequisites: "Certainty in Result, Celerity in Action, Painlessness in the Endurance, and the Maintenance of a Decorous Solemnity." There should be no public display, no *pompa Mortis*, no exchange of civilities between prisoner and sheriff. The narcotic cup, it seems to the writer, would do away with all the objectionable features alluded to in this communication.

Frederic Rowland Marvin.

Albany, N. Y.

The Hereditary Transmission of Syphilis.—Neumann believes that the maternal syphilis has a more intense effect on the progeny than that derived from the father. Infection of the mother after conception has taken place may be transmitted to the fœtus even during the later months of pregnancy. His observations are based on a series of fifteen families in private practice, and he finds that in many marriages, where the offspring are afflicted with hereditary syphilis, the mothers remain free from the disease, while the fathers present evidences of old or recent disease. Without distinct evidences of a former infection it is not wise to make a diagnosis of latent syphilis in the mother. The manner in which the paternal transmission takes place has been proved and the spermatic fluid carries the virus which infects the embryo. But the idea of an exclusive maternal transmission cannot be recognized, nor can that of an infection through the placenta alone.—*Wiener klinische Wochenschrift*

Progress of Medical Science.

The Boston Medical and Surgical Journal, July 14, 1904.

Functional Albuminuria, with a Report of a Case.—J. Bergen Ogden reports this case: The patient was a boy of nineteen years, and apparently in every way healthy. Aside from a neurotic temperament, the albumin in his urine was the only thing to attract attention. The urine was generally free from albumin on rising in the morning. The amount then rose to a maximum of 0.05 per cent. in one instance. The quantity of albumin was usually small, its fluctuation being largely due to the amount of exercise taken, and also, to a less extent, to the intake of food, irrespective of its quality or quantity. Generally, the largest amount of albumin was found in the evening or after he had reached home and had had his dinner. On one occasion no lunch was taken, but he remained active; the amount of albumin was apparently not affected. On another day he lay down for four hours. This resulted in a complete disappearance of the albumin at that time. In the majority of instances the specific gravity was in the neighborhood of 1.021. The percentage of urea varied between 1.01 and 3.68. Since October, 1903, a number of thorough microscopical examinations of the urine have revealed no casts. The writer believes that the possibility of an incipient chronic disease of the kidneys can be eliminated. The treatment is simple and the reverse of what is ordinarily considered suitable in renal disease. Good, simple food, fresh air, vigorous exercise, and tonics are suggested.

Experimental Decapsulation of the Kidneys. N. H. Gifford gives the following summary: Following the decapsulation of kidneys in rabbits, in normal dogs, in dogs with induced nephritis, in dogs with infarcted kidneys, but with additional work thrown upon them, the writer finds the following conditions: In all of his cases of two days and under and in the controls, the entire thickness of the capsule had been removed over two-thirds of the surface by the operation of decapsulation. There is a certain amount of intracapsular tension in undecapsulated kidneys, normal or with nephritis, as shown on removal of capsule. There is an immediate increase in size of decapsulated kidneys persisting up to one month at least; afterward, a decrease to approximately normal size complete at the end of six months. There is congestion, moderate in degree, most marked in the intertubular blood-vessels in the cortex, lasting three to five days after the operation. No histological change in the renal epithelium follows the operation of decapsulation of kidneys. A new capsule, very vascular, at first two to four times the thickness of old, is well marked at the end of eight days. At the end of six months it returns to approximately the normal thickness and vascularity. The new capsule arises chiefly from the connective-tissue cells of the intertubular connective-tissue, but in part from the retroperitoneal connective-tissue which is present in the new bed of the kidney. No new vessels are formed which anastomose with those of the kidney. The increase in size is due primarily to the increase in blood-supply, possibly resulting from the removal of the capsule.

Journal of the American Medical Association, July 16, 1904.

Pin in the Appendix.—Evan O'Neill Kane reports this case. The appendix was found imbedded in adhesions, greatly thickened and friable, its hue dark crimson, almost purple, with two points of complete mortification. The organ measured but two inches in length. In the appendix was found a pin slightly bent in the middle and covered heavily with concretions, except toward the point. It must have entered the appendix head first. The patient had never complained of any symptoms which pointed to its possible presence except an attack of appendicitis four years prior to operation.

Will the Long-continued Administration of Digitalis Induce Cardiac Hypertrophy?—Frank W. Wynn says that various authors make the statement that digitalis will cause cardiac hypertrophy, but he was not aware that experiments had been made which prove it. He took healthy Belgian hares, giving both experimental and control animals, and after work covering a period of 120 days, concluded that the difference in heart weight, when taken in conjunction with the general loss of weight of the experimental group and the gain of the control animals, showed that digitalis did produce a slight degree of cardiac hypertrophy. But that the remedy is responsible for hypertrophy to any great degree in valvular heart disease seems doubtful.

Falling of the Hair.—R. A. McDonnell says the most common cause of premature loss of hair is seborrhœa and the resulting eczema. Barber shops were greatly at fault in the spread of seborrhœa, as also were head-rests of operating chairs, hat-pegs at clubs, backs of railroad seats, etc. Hair dyes and bleaches are certainly responsible

for no small amount of baldness. The practice of saturating the hair with water is a damaging one. The pressure by stiff hats is another cause. The various diseases causing dandruff is the most fertile source of alopecia. Next to dandruff is heredity. Other causes of premature loss of hair, their diagnosis, prognosis, and treatment were considered in the paper merely for the sake of completeness. The object of the paper was to call attention to the great variety of causes which may produce falling of the hair, and to show that no treatment is liable to be successful unless based on a proper analysis of the case.

Does Gonorrhœa Cause Prostatic Hypertrophy?—Edward L. Keyes, Jr., expresses his views in the following summary: (1) Among 433 cases suffering from prostatic hypertrophy, only 18 show clinical evidence of previous prostatitis. (2) These 18 present no marked difference in point of size of the prostate, or of beginning of the disease to differentiate them from the remaining 415. (3) Comparison of these 18 cases of chronic prostatitis without hypertrophy shows that the proportion of such cases suffering from prostatic hypertrophy varies little from the normal. (4) Prostatitis lasting more than ten years probably tends to produce prostatic atrophy rather than prostatic hypertrophy. (5) Therefore, if it is true that hypertrophy of the prostate is pathologically referable to inflammation, the clinical data suggest that this inflammation is either early gonorrhœa of relatively brief duration or some obscure sclerotic process associated with advancing years. (6) The late date at which prostatic hypertrophy begins and its infrequency, compared with that of early gonorrhœa, make it seem clinically most improbable that early gonorrhœa is the cause.

Radium and Its Therapeutic Possibilities.—Wm. Allen Pusey says that radium produces effects upon the tissue closely analogous to, if not identical with, those produced by *x*-rays. The indications for its therapeutic uses are along the same lines as those for *x*-rays. Future experience only will determine which of the two agents will be of the greater practical value in meeting these indications. In the far greater number it seemed to him that the *x*-rays would have the larger field of usefulness. It is probable that Becquerel rays will be efficient only to a very limited depth. Becquerel rays have theoretical advantages over *x*-rays in the accuracy of dosage and in the ease of application at inaccessible points. They have a disadvantage in the relatively small quantity of energy available, and in the limitation accordingly of any single efficient exposure to a very small area. It is highly improbable that radium is going to be of epoch-making importance in therapeutics. It supplements and may add materially to the methods now at command for using actinic radiant energy in therapeutics. If it becomes less expensive and obtainable in relatively larger quantities, it may supplant to a limited extent the use of *x*-rays and ultra violet light, although this is not probable. Finally, he believes the therapeutic possibilities of radium has rather been overstated.

Medical News, July 16, 1904.

Cocainism.—Charles T. Douglas speaks of the particularly injurious effect on the skin that cocaine produces. It causes abscesses and other sores. Hallucinations are often present in cocainism. These often relate to the skin. The patient will believe, for example, that insects are burrowing in the cuticle. Hallucinations of hearing may exist, and the patient thinks that he hears "voices." Emaciation is almost a universal symptom. Cocaine victims are greatly distressed by insomnia. Cocainism is one of the most readily cured of drug addictions. It is remarkable how promptly these patients usually return to a normal state by proper sanatorium treatment.

The Extraperitoneal Relations of the Appendix Vermiformis to the Posterior Surface of the Cæcum, with the Report of a Form Hitherto Undescribed.—C. E. Briggs describes an interesting case. At an operation for appendicitis in the case of a girl of twenty years, the cæcum and appendix were readily located. The appendix emerged from the cæcum at the point noted in the large majority of cases—a little internal and slightly posterior to the projection of the caput. The end of the cæcum was drawn upward, making prominent the line of reflection between the cæcal and parietal peritoneum. On careful inspection it was seen that what appeared to be the adherent tip of the appendix was merely a constriction narrowing the appendix to about one-quarter its proximal diameter. From this constriction the remainder of the appendix was seen in dim outline to lie extraperitoneally along the cæcum as far as the line of peritoneal reflection mentioned, from which point it was lost to view in the retrocæcal connective-tissue. The extraperitoneal part of the appendix was 1 cm. long. A short incision was made along the line of peritoneal reflection and the retrocæcal connective-tissue separated along the appendix to its tip. This part of the organ was 1 cm. long, making the entire appendix 4.5 cm. in length, the free mesenteric part 2.5 cm., the extraperitoneal part 1 cm., the retrocæcal part 1 cm. The writer then gives a list of the types of extraperitoneal relations of the appendix to the posterior surface of the cæcum and ascending colon, which have been recorded. The writer thinks it probable that in this case reported the tip of the appendix became adherent rather late in the descent of the cæcum, so that only a small part became lodged in the retrocæcal connective-tissue. The part of the appendix between the retrocæcal tip and the mesenteric part became adherent in some way to the cæcum, the adherent peritoneal surface changing to connective-tissue.

Treatment of Lobar Pneumonia in the Adult.—William H. Dukeman believes that in pneumonia toxæmia calls for the first attention. To combat this, the skin and bowels are the main avenues through which this may best be accomplished. In the early stages a good sponge bath of hot water and soap, followed by a hot foot-bath containing mustard, will act well on the skin. The foot-bath is best taken in bed by putting the feet into a small tub under the blankets. Hot lemonade aids free perspiration. The foot-bath may be continued from one half to one hour. The patient should sweat for about half an hour freely, when he should be dried and rubbed well with coarse towels to get up a good cutaneous capillary circulation. The chest is then encased in the cotton jacket. In case of any pain, a mustard plaster is placed over the area, and after it is removed, the chest is well oiled with camphorated oil. For the bowels it is well to give 2 or 3 grs. of calomel in divided doses of half a gr. every half hour, followed in six to eight hours by a Seidlitz powder or dose of Epsom salts. The action of the kidneys is best kept up by the free administration of pure water at the temperature of the room. The least medicine given the pneumonia patient the better are his chances of recovery. The teeth and mouth must be kept sweet and clean. A daily sponge bath with tepid water and soap and a daily dose of a mild saline aperient should be given. Plenty of pure water at room temperature should be given, and all food should be liquid—chiefly milk. To help ward off heart weakness, strychnine is given. In cases of high fever and little or no delirium, and when the heart sounds have lost their force, half an ounce of whiskey or brandy every three hours is indicated if the patient is more quiet after its administration. If he becomes restless, it must be stopped. In case of cyanosis, champagne or the aromatic spirit of ammonia is given, as well as inhalation of oxygen. A mustard plaster over the heart is also of service. The writer advocates strongly the use of oxygen.

New York Medical Journal, July 16, 1904.

Some "Liver" Cases.—J. H. Carstens says that formerly all abdominal troubles were referred to the liver, were they intestinal indigestion, autointoxication, constipation, or diarrhœa. It was such a handy thing to say it was "the liver." Cathartics were used and with benefit because of the depletion of the abdominal viscera. Flushing the bowels expelled the bacterial invasion. Vast strides, however, have been made in diagnosis, and to-day we are able to make correct diagnoses, and only in a few instances are we obliged to resort to exploratory operation. Thinking that a few illustrations of the various phases might be interesting, he picks out six cases in which he had operated during the past year, each one of which teaches a different lesson in the diseases of the liver.

Congenital Inspiratory Laryngeal Stridor, with Report of a Case.—Samuel Kohn presents a child, two years old, who has been suffering with marked laryngeal stridor since her birth. She had been under his care since she was eleven weeks old. A very difficult laryngoscopical examination revealed a small epiglottism involved at its edges, giving it the appearance of a hollow cylinder; the aryepiglottic folds seemed hypertrophied and flabby. The encroachment upon the introitis laryngis, by the infolded epiglottis and the flaccid, hyperthrophied aryepiglottic folds, and the still further narrowing of the opening during inspiration by suction inward of these soft parts, seemed fully to explain the stridor. A consideration of the diagnosis, causation, and treatment of laryngeal stridor then follows.

The Dysentery of the Tropics, with Special Reference to Our Insular Possessions.—Frederick M. Hartsock, U. S. A., says the types of dysentery met with in our insular possessions may be sharply separated into the following: (1) Catarrhal; a simple form due to the natural hyperæmic condition of the intestinal mucosa of the Europeans in the tropics, plus some irritating substance, bacterial, parasitic, or chemical, which gains access to the intestinal mucosa. (2) Amœbic; here is seen the greatest amount of destruction of intestinal mucosa and is depend-

ent on or associated with a parasitic amœba. (3) Acute specific: the lesions are in the large and lower part of the small intestine and mesenteric glands, and in which is found a bacillus "related in its cultural and physiological properties to bacillus typhosus," which agglutinates with the blood of patients with this form of dysentery. The most simple cases of intestinal inflammations in the tropics should receive prompt and vigorous treatment, for ever before us is the chance of psilosis succeeding a refractory case. Sprue is one of the most frequent sequelæ of the amœbic form, especially in the Philippine Islands. Acute specific dysentery, as seen in the Philippines, is one of the most dangerous affections of the intestinal canal, excepting cholera. The infection may be so overwhelming that death follows soon after the onset.

American Medicine, July 16, 1904.

The Carotid Body; Anatomy, Histology, Embryology, and Tumors Arising from It.—John Funke describes the carotid body as being the size of a grain of rice, oval in shape, red, firm, and vascular. In structure and consistence it resembles the superior cervical ganglion. By means of a small band it is attached to the carotid at the bifurcation. This body is in relation with the "nervis mollibus," formed by a plexus from the superior cervical ganglion. A branch from the glossopharyngeal nerve, after sending a branch to the "nervis mollibus," penetrates the ganglion. Before entering the ganglion, however, it receives another branch from the vagus. To find the ganglion one need only remove the common carotid, together with about an inch of the internal and external carotids. From his own investigations, the author does not think that it is possible to believe that the carotid body is present as often as is generally thought. The body is enclosed by a fibrous capsule, the density of which varies at different points. This fibrous tissue contains many blood-vessels. The lobules of the body are composed of collections of cells with no definite arrangement. There are various theories concerning the embryology of the carotid body. The tumors of this body occur especially in adolescence and in adult life. Neither sex seems predisposed. In two cases out of fourteen there was a history of malignant disease in the family. Heinleth says that the carotid body develops until the age of puberty, when it either atrophies, or the development is arrested; if the body continues to grow, a tumor is formed. As to the diagnosis of these tumors, the position is first noted—anterior to the sternomastoid muscle extending from the superior margin of the thyroid cartilage to within a few centimeters of the angle of the jaw; the evident pulsation, but no expansion; the murmur over the growth, but no more intense than over the carotid artery; the synchronous pulsation in both temporals; the boggy or elastic character of the tumor; the movable skin over the growth; a history of long standing and of slow enlargement; occasional vasomotor disturbances.

Fractures of the Extremities: a Report of 1,000 Consecutive Cases, Verified by Radiographs. G. G. Ross and M. I. Wilbert point out various interesting facts in connection with their study of this series of cases. It has been suggested that a fracture of the carpal bones not infrequently occurs in falls from the bicycle. The writers note that fractures of one or more of the carpal bones are not nearly as frequent as they were four or five years ago. The bicycle is not in such general use as it was several years ago. The importance of the routine use of the Röntgen rays in all cases of injury to bones, is emphasized. Of these thousand cases, 642 were of the upper, and 358 of the lower extremities. A total of 517 of the cases involved the right, while 483 involved the left side of the patients. There were 791 male patients and 209 female. The greater number of fractures occur between the ages of eleven and forty. Up to the tenth or even twentieth year, injuries at or near the elbow are comparatively more frequent than any others, and are among the most difficult to diagnose satisfactorily. The reason is that the peculiar and varying development of the lower end of the humerus, differing as it does even in individuals of the same age, is likely to be misleading unless both elbows are carefully examined. In children, especially in boys of ten or twelve, a marked separation of the epiphysis of the inner epicondyle is not of infrequent occurrence. Of the fractures at or near the wrist, 238 in number, 96 involved the radius alone, 68 were fractures of the radius with an accompanying fracture of the ulna about on the same plane, while five were fractures of the lower end of the radius with a fracture of the ulna higher up. There were also 9 simple fractures of the ulna. Out of a total of 50 cases of fracture of the forearm, 15 involved the radius alone, 8 were of the ulna, and 27 were of both the radius and the ulna. Of 39 fractures of the leg, 15 were of the shaft of the tibia, 7 of the fibula, and 17 involved both the tibia and fibula. Injuries involving the ankle-joint are among the most trying with which the medical practitioner has to contend. Because the patient can often move the foot, and even walk on it, he refuses to have the joint immobilized or properly treated. Of the 80 fractures of the foot, 35 were of the metatarsal bones, 28 of one or more of the phalanges, 15 of the metatarsal and tarsal, and 2 of the metatarsal bones, including one or more of the phalanges. With the exception of a few minor details, the writers believe that their figures present a very fair average of the number and kinds of injuries that our osseous framework is subject to at the present time.

The Concussional Vertebral Reflexes.—Albert Abrams declares that concussion of the vertebral spinous processes, whether by manual manipulation or by vibratory massage, will induce palpable lung, heart, liver, spleen, stomach, and intestinal reflexes depending upon the vertebræ subjected to concussion. The writer employs a dental mallet weighing about 4 ozs. and a pleximeter of felt. The reaction on the viscus is of short duration, hence the objective demonstration of the viscual reflex as ascertained by percussion must be executed immediately, after vertebral concussion. It is contended that it is impossible in arteriosclerosis to produce variations of the aorta that occur normally. The aorta dilates if the region over the arch is struck with the percussion hammer, while it shrinks in size if the blows are struck in the epigastrium. But the writer believes that the phenomena have been misinterpreted. What is really elicited is a circumscribed lung contraction adjacent to the part struck on the chest by the hammer, and the blow on the epigastrium merely causes the collapsed lung area to dilate, thus supplanting dulness by resonance. Concussion of the dorsal vertebræ, 8, 9, 10, 11, and 12, will cause dilation of the aorta, and the course of the arch of that vessel can easily be defined, owing to the dulness obtained by strong percussion after vertebral concussion. Concussion of the seventh cervical vertebra causes the dulness to evanesce at once. The lung is in no wise implicated in the percussion changes. Invoking the aortic reflexes may be important in determining the elasticity of the aorta, and thus recognizing early arteriosclerosis. One may elicit the heart reflex of contraction without inducing the lung reflex of dilation by concussion of the seventh cervical vertebra. There are many indications for the practical application of the heart reflexes, one of which is the differentiation of a dilated heart from a pericardial effusion. In effusion the area is uninfluenced. When the skin in the region of the lower liver border is irritated, the lower liver border may be observed by percussion to recede half an inch or more. The faculty of the liver and spleen to contract is diminished in certain pathological conditions, and when such conditions are fully recognized the liver and spleen reflexes will become endowed with a definite diagnostic significance. When the first three lumbar vertebræ are concussed, the tympanicity of the stomach and intestines will be supplanted by dulness. The writer describes a manœuvre for inducing the stomach reflex of contraction, by which the determination of the motor power of the stomach may be accomplished, as well as defining its area. The presence of a neoplasm and its association with the stomach may be shown to exist by aid of the stomach reflex, for elicitation of the latter will cause a dislocation of the growth upward and to the left.

The Lancet, July 2, 1904.

On the Frequency of Aseptic Necrobiosis or Red Degeneration of Fibromyomata of the Uterus.—Frank E. Taylor reports two such cases. The appearance of such a tumor is striking; it is usually single, with a well-marked capsule, distinctly red, mahogany or liver colored, fleshy looking, and loose textured, having been compared to raw beef steak. There is nothing in its external appearance before section to indicate its nature. In the majority of gynecological textbooks there is not the slightest hint that such a condition may occur. Tables are given based on the material obtained in the pathological department of the Chelsea Hospital for Women at St. Thomas's Hospital, giving a total of over six hundred specimens of fibromyomata of the uterus examined and 6 per cent. showed aseptic necrobiosis, or red degeneration.

Note on the Concentration of Chloroform Vapor in Air Drawn from Beneath the Skinner Mask.—W. Legge Symes presents certain observations undertaken at the suggestion of A. D. Waller, and from these it appears that, at ordinary room temperatures, with moderate and approximately equal quantities of chloroform, the Skinner mask yielded vapor of fairly uniform concentration between the desirable limits of 1 and 2 per cent., but reaching as high as 3 or 4 per cent. when the chloroform was copiously applied. The more open of the two fabrics employed gave vapor of higher and, with douches, less uniformly sustained concentration than the closer one. Comparison of the drop and douche methods showed that a desired concentration is as certainly attained and more

uniformly sustained by the former. It was reasonable to conclude that changes in respiration will produce variations in concentration, and it was emphasized that fall in frequency and depth of respiration may lead to inhalation of dangerously concentrated vapor, even when the amount of chloroform used is not excessive.

Diabetic Neuritis.—F. W. Pavy points out that an altered vascular state emanates from nerve lesions through the influence exerted on the functional capacity of the vessels. Nutritive operations are liable to be influenced secondarily. He refers to the trophic condition arising from diabetic neuritis, and says that trophic lesions may occur in connection with diabetes as a primary result of the effect of the sugar abnormally passing through the system. Diabetic neuritis is a very variable affection with respect to location, but its development exhibits a symmetrical character The lower limbs suffer more frequently than the upper. Sometimes the neuritis is localized in a single nerve. Looking at the circumstances existing, it is not surprising that we should have a protean class of symptoms to deal with in diabetic neuritis. Some few cases had fallen under his observation in which anginal symptoms had existed in connection with the diabetes, probably arising from involvement of the pneumogastric nerve. A toxic factor operates in peripheral neuritis, and in books it is stated that a toxic agent stands as an operative factor in diabetic neuritis as well. In Ross and Bury's work on "Peripheral Neuritis" it is stated that certain facts seem to indicate that the neuritis is not due to an excess of sugar in the blood. His experience was diametrically opposed to this allegation acquitting the sugar. Neuritis does not occur where the sugar is kept down by treatment. Conjoined with the dietetic and codeina or opium treatment for the diabetes, he has obtained beneficial effects from the administration of 5 grs. of iodide of potassium and 10 grs. of bromide of ammonium thrice daily. If there is much superficial pain he applies cautiously linimentum aconiti.

The Treatment of Congenital Equinovarus During Early Infancy.—E. Laming Evans says that during 1903 he had treated fifty-three cases of congenital equinovarus. The method adopted by him was a slight modification of that first introduced by W. T. Little and emphasized by W. Adams. It consists of two stages: (1) The correction of the varus, and (2) the correction of the equinus. Stage 1 is commenced as early as possible, and consists in the subcutaneous division of the tendons of the tibiales anticus and posticus and flexor longus digitorum above the ankle-joint with immediate rectification of the varus as far as possible with subsequent manipulation to complete the correction, and in the intervals of manipulation the retention of the foot in the improved position by means of a padded malleable-iron splint. The time taken to correct the varus averaged in his cases thirty days. Stage 2 is then commenced by subcutaneous division of the tendo Achillis with immediate rectification as far as possible and subsequent manipulation to complete the correction of the equinus, with retention of the foot in the intervals in a padded tin shoe of special design. The treatment of congenital equinovarus may be divided into two main schools: (1) those who treat during early infancy, employing various methods; and (2) those who wait till childhood has well advanced and then correct by one of the various major operative procedures. The arguments used in favor of the latter are the dangers of chloroform during early infancy, the risk of ulceration from pressure of the plaster cast, the insufficient support of the latter because it softens with the urine, the long course of treatment during which the child suffers pain, and the parents are much inconvenienced. The chloroform argument is twice answered; for first, the risk in the hands of a skilled anæsthetist is no greater at the age of eight weeks for simple manipulation of tenotomy than it is at the age of six years for extensive tarsectomy; and, secondly, in ten out of the eleven cases in this series no chloroform was used. The plaster-of-Paris argument does not apply to this method as it was not used.

Berliner klinische Wochenschrift, June 27, 1904.

The Physiological Action of Radium.—J. Wohlgemuth has investigated the effects of this substance on the principal constituents of the body—albumin, carbohydrates, and fat. These were exposed to the radiations daily for fifteen to thirty minutes, and at the end of five days analyzed. Repeated observations were entirely negative, the composition of the material remaining unchanged. It was also found that no elective action on the lecithin of fat resulted, as stated by other observers. The action of radium on the autolysis of tuberculous lungs was also studied, and it was determined that exposure of a portion of this tissue to radium in an incubator resulted in the absorption of an amount of nitrogen four times greater than that of the control specimen. This phenomenon he explains by assuming that the resistance to autolytic processes after death is lessened by the action of radium. If this assumption is correct, then the difference in the amount of nitrogen would become less as the resistance in the control specimen was overcome. This was found to be so as a matter of fact, and after ten days the amounts of nitrogen in solution were practically the same in both and continued so.

The Agglutination of the Typhoid Bacilli in Icterus and Hepatic Diseases.—H. Kammerer has examined fifty cases of icterus, with reference to the behavior of the Widal reaction, and found that among this relatively large number agglutination at a dilution of 1:50 occurred only once, while in the majority of instances it took place at 1:10 or less. The patients included fifteen cases of cirrhosis of the liver, eight of carcinoma of the liver, two of myocarditis, and one each of carcinoma of the gall-bladder and hepatic syphilis. It seems, therefore, that the theory which assumes that agglutination is brought about by the presence of biliary elements in the circulating blood finds little support from this investigation. The author believes that it is more probable that the presence of an icterus produces agglutination of closely-related bacterial species—a so-called "group agglutination." The purity and freshness of typhoid cultures employed for the Widal tests should always be definitely ascertained, and tested by controls. It is also well to confirm the results by the use of Ficker's diagnosticum. This investigation shows that the Widal reaction is still the most reliable test for the differential diagnosis of typhoid fever, especially if a positive reaction results with a dilution of 1:100 or over.

The Effect on Secretion and Motility of the Stomach of Endofaradization and Endogalvanization.—A. Borri has made a careful study of this subject on a large number of patients in the Augusta Hospital in Berlin, in order to determine whether electrotherapeutics would be attended with equally favorable results when applied in gastric disorders, as in other parts of the body. Most observers have contented themselves with external applications of electricity, whereas the author has made a special study of the endogastric methods. Thus far no consensus of opinion has been reached, some writers ascribing a stimulating action to the faradic current and an anæsthetizing influence to the galvanic current, while others claim that the effect of faradization is largely sedative. Borri studied the effect of the currents on secretion in ten persons, two of whom were perfectly normal as regards their gastric and intestinal functions. It was found that the results as regards any changes in the secretions were entirely negative, and the author believes that in those instances in which an increase was noted after the application of electricity the effects were due, not to the current, but to the manipulations which the procedure entailed. The pepsin content was also found unchanged in these experiments, or, as in a few cases, was slightly diminished in amount. Gastric motility was studied by giving the patients test breakfasts on two successive days, on one of which endofaradization was also done. No constant differences were noted, and in two cases of atony no effect was observed which could be ascribed to the electric current. In contrast to these negative results was the effect on the sensibility of the stomach. Here a well-marked anodyne effect followed the application of the galvanic current when the negative pole was placed in the stomach.

Münchener medizinische Wochenschrift, June 28, 1904.

Radioactive Substances in the Nauheim Springs.—Schott briefly notes the results of the observations which have been made on the waters of these springs with reference to the presence of radioactive materials. The sediment from two of the main springs was found to possess a radioactivity varying from 23 to 34. This is a higher figure than any previously noted in other well-known deposits of radioactive clays or other substances. In other springs in the neighborhood the figures rose to 250. Knowledge of these facts may explain the hitherto doubtful efficacy of certain balneological therapeutic measures.

Muscular Dystrophy Following Trauma.—S. Hösslin reports a case of muscular dystrophy in a man of twenty-one, which ostensibly followed a traumatism of the shoulder. More careful inquiry elicited the fact that a muscular weakness existed before the injury was sustained. It seems fair to assume, therefore, that the dystrophy was present before any injury took place, and the same was merely aggravated by the latter. There was no hereditary history. The case teaches that the scientific value of statements made by injured persons as bearing on the etiology of a condition of this kind should be accepted with doubts.

Researches on the Bacteriology of the Lower Air-passages and the Pathogenesis of Pneumonia.—H. Durck has already shown, by means of animal experiments, that

the deeper air-passages are inhabited by bacterial flora which, under ordinary circumstances, are not pathogenic, but may readily become so when any lesion of the mucous membrane occurs. Inhalations of dust which caused irritation, by either mechanical or chemical means, were proved to be the most common factors, but the writer also succeeded in showing that exposure to cold and the subsequent chilling of the body were followed by the same result. An animal kept in an incubator at a temperature of 37-38° C. for twenty-four hours, and then plunged into ice-water, soon after became afflicted with pulmonary pneumonia. These assertions have been combated by other writers, but the author claims that, as the results of further extended observations, it may be stated that, although the pneumococcus may be accepted as the immediate cause of genuine fibrinous pneumonia, it can bring on the disease only when its virulence is so great that as soon as it enters the air-passages it is able to overcome the natural protective barriers, or when the mucous membranes have been weakened by some other factor. These observations have been confirmed since their publication by other investigators. The author has also repeated his own experiments, but, instead of exposing the animals to a high temperature, he merely immersed them up to the neck in cold water for a period of from two to ten minutes. In about one-half of the cases more or less extensive pneumonic processes developed within a few days. Marked hemorrhages were present in almost all instances.

Coxa Vera.—F. Härting discusses the etiology and treatment of this condition and reports a case in a woman of twenty-six who came under his care for a simple fracture of the shaft of the femur. The patient at the same time presented a coxa vera. There was apparently no history of rickets, but about eleven years previously she had an attack of pain in the same leg, which disappeared under rest and massage. For the succeeding six years it recurred annually, and the limb underwent a gradual shortening, but then the pain no longer returned. This may possibly have been one of those instances of late or retarded rachitis, which becomes localized in some spot, as here, in the neck of the femur. Although rachitis, osteomalacia, tuberculosis, arthritis deformans, fractures, etc., may be regarded as predisposing causes, the immediate cause is undoubtedly mechanical. Coxa vera results from the weight of the body bearing down on a weakened neck of the femur, which has become so as the result of some of the affections just noted. The author has also observed that the condition is ordinarily found in young men who have experienced a rapid growth and present a well-marked skeletal development, but an insufficient development of the musculature. The treatment in most cases should be an expectant one, the patient being kept in bed for a prolonged period, with an extension apparatus on the leg. When the pain disappears the treatment may be supplemented by massage, active and passive movements. Operative interference should only be considered after the inflammatory symptoms have subsided and when the deformity is marked. Osteotomies of various types have been suggested, together with division of the adductors, and, in extreme cases, resection of the hip-joint. The most successful osteotomy has thus far been that suggested by Hoffa—the oblique subtrochanteric.

French and Italian Journals.

Radiograph and Chemical Analysis of Calcified Arteries.—A. Gascard declares that it is rare to see a radiograph which gives an outline of the arteries. These vessels are normally as transparent as the surrounding muscular tissue. When arteries become atheromatous and calcified, they may become as opaque as osseous tissue. In a patient who entered the hospital last summer the tibial arteries, anterior and posterior, the peroneal, the cubital, radial, deep palmar arch, and the collateral artery of the thumb were all shown in the radiograph that was taken. The patient was a man of seventy-four years. Later the patient died from the effects of an accident, and chemical examination of these arteries revealed the presence of calcium phosphate, calcium carbonate, and magnesium phosphate. The composition of the mineral matter of these arteries was the same as that of the ashes of bones.—*La Revue Médicale de Normandie*, June 25, 1904.

A Special Necrotic Change in the Hepatic Cells in Tuberculous Infection.—B. Pernice finds alterations in the livers of persons affected with tuberculosis when there is no involvement of the liver itself. The most common alterations are the granulo-fatty, amyloid, and coagulation necrosis. Epithelial necrosis is much more common in the livers of tuberculous subjects than is generally believed. It is due to the toxins circulating in the blood. In such cells the nucleus and cell protoplasm have become atrophied. In a case observed by the author the alterations were as follows: There was a filamentous condition of the protoplasm, which did not stain uniformly; the nucleus was enlarged, and there were many vacuoles in the cell body. In some the nucleus was entirely gone. He calls this condition vacuolar necrosis.—*La Riforma Medica*, June 1, 1904

Note as to the Question of the Scarlatiniform Eruptions that Present Themselves in the Course of Diphtheria.—Carle Francioni states that the differential diagnosis is difficult between the different forms of eruptions occurring during the course of diphtheria. These may arise from true scarlatina or may be late manifestations of the use of antitoxic serum. Still it is very important to know whether we have to deal with a harmless serum eruption or with a dangerous complicating disease. Lobligois has observed that on examination of the blood, polynucleosis is more marked in scarlatina than in serum eruptions; eosinophiles are rarer in scarlatina; anomalous forms are found in serum that are absent in scarlatina. On examination of the urine the diazo-reaction is frequent in scarlatina, and rare in diphtheria. If this reaction is found, the eruption is that of scarlatina. The author believes that the eruptions of serum, occurring late, are coincident with and dependent upon the production of the specific antitoxin in the blood. A test for the presence of this may be made by the presence of pricipitin in the blood. The author has made this test in five cases of true scarlatinal eruptions observed by him, in none of which was precipitin found.—*Revista di Clinica Pediatrica*, May, 1904.

Peritonitis.—F. Mariani writes of the conclusions derived from his researches on peritonitis. They referred to the power of the peritoneum to react against pathogenic germs of different virulence, and against the same germ in different strengths; that is the power of the peritoneum to destroy pathogenic bacteria; also as to the action of innocuous germs on a peritoneum which had been subjected to some previous irritation, as by laparotomy, or the use of irritating drugs. He further studied the conditions under which germs inoculated at a distance affect the peritoneum, either by direct contact or through the circulation. He concludes that the peritoneum possesses a destructive power that is slight for some virulent germs, such as the pneumococcus; but has a powerful destructive action on others, staphylococcus and colon bacillus. This destructive power is lessened by previous operation or irritation; it is lessened at first by laparotomy, but if the subject live for fifteen or twenty days the resistance of the peritoneum becomes greater. Irritant drugs have the same action. Drastic purgatives which increase peristalsis, lessen the resistance of the peritoneum, while morphine increases it. If the bacterial infection is rapid and acute, the colon bacillus is not found in the peritoneum, but if the case is chronic these bacteria are found in life and after death on the peritoneum.—*Il Policlinico*, May, 1904.

Sarcoma of the Testicle.—Malloizel and Claret report this case. The patient was a man aged twenty-seven years. He was a tuberculous syphilitic. He came to the hospital on account of an enlarged testicle which was beginning to give him pain. The tumor was firm in its lower part, but pseudo-fluctuating above. There was no special sensitiveness perceptible. No lumbar ganglia could be felt. The urine was free from albumin. There were a few râles in the lung just below the right apex. Operation was decided upon, although the prognosis as to recurrence was grave. The testicle was removed as well as a part of the cord. Five days later the wan and anxious aspect of the patient was marked. The urine was clear and normal in quantity. Œdema gradually developed. Pain in the region of the two kidneys distressed the patient. Three weeks after the operation, anuria developed and this condition continued for eight and a half days, when the patient died. There had been no hæmaturia. At autopsy no recurrence was noted in the scar. An enormous soft, pliable mass had destroyed and replaced the left psoas muscle. On the right there was a small mass of the same kind. Microscopical examination of the testicle revealed a fibrosarcoma. In the lungs were found epitheliomatous, sarcomatous, and tuberculous tissue. The epitheliomatous tissue was far more abundant than the sarcomatous. The writers believe that the tumor of the testicle had been primarily mixed, but that the sarcomatous tissue had increased while the epitheliomatous tissue had disappeared. The kidneys showed the lesions of acute nephritis. The anuria was due to the nephritis, but the cause of the nephritis was difficult to determine. Acute nephritis in a cancerous patient is very interesting without a neoplastic focus in the kidney to cause the epithelial proliferation.—*La Tribune Médicale*, June 18, 1904.

Book Reviews.

Die Syphilide (Syphilis der Haut und Schleimhaut). Von Dr. Jessner. II Teil: Therapie. Würzburg: A. Stubers, 1904.

This is No. 12 of Jessner's small works on dermatological subjects. The questions here discussed are time-honored but have an ever-present interest for those engaged in the diagnosis and cure of skin and mucous membrane syphilides.

Anæsthesia in Dental Surgery. By Thomas D. Luke, M.B., F.R.C.S.E., Anæsthetist to the Dental Hospital, The Deaconess Hospital, and Instructor in Anæsthetics to the University Surgical Classes, Royal Infirmary, Edinburgh. With twenty-eight Illustrations. New York: Rebman Co., 1903.

So great a variety of methods of making dentistry painless have arisen that a volume devoted to the subject seems not amiss, especially as no work of which we know covers this field exclusively. The aim of the present volume is practical utility, with descriptions of way of applying the various local and general anæsthetics.

The use of chloroform and its abuse are considered at length, and accidents are discussed from standpoints of prevention and relief.

Des Haarschwunds Ursachen und Behandlung. Vierte Auflage. Von Dr. Jessner. Würzburg: A. Stubers, 1904.

This is the first number of Dr. Jessner's Dermatologische Vorträge für Praktiker. It is a fifty-page brochure, which aims to explain why the hair falls and how to prevent and cure it. Many of the suggestions are very practical, and the subdivisions of the subject are scientific.

A Textbook of Operative Surgery, Covering the Surgical Anatomy and Operative Technique Involved in the Operations in General Surgery. Written for Students and Practitioners. By Warren Stone Bickham, M.D., Assistant Instructor in Operative Surgery, College of Physicians and Surgeons, New York. Late Visiting Surgeon to Charity Hospital, New Orleans. Second Edition. New York, Philadelphia, London: W. B. Saunders & Co., 1904.

In the short time that has elapsed since the first edition of this work, there has very naturally arisen no need for extensive alterations in its text or in the illustrations. A few typographical errors have been corrected, but the book in its entity is practically unchanged.

Medical Diagnosis. A Practical Treatise on Medical Diagnosis for Students and Practitioners, by John H. Musser, M.D., Professor of Clinical Medicine in the University of Pennsylvania; Physician to the Philadelphia and Presbyterian Hospitals; Consulting Physician to the Woman's Hospital of Philadelphia and to the West Philadelphia Hospital for Women, to the Rush Hospital for Consumptives and the Jewish Hospital of Philadelphia; Fellow of the College of Physicians of Philadelphia; Member of the Association of American Physicians; President of the American Medical Association, etc. New (5th) edition, revised and enlarged. Philadelphia and New York: Lea Brothers & Co., 1904.

The natural growth of diagnosis of internal disease has been reflected in the various editions of the work before us. In the present edition the author has rearranged the whole book, so that its usefulness has been increased. The older theoretical portions have been condensed to make room for new material, but so great was the amount that another hundred pages had to be added. Not only has the text been enlarged but the illustrations have been doubled in number, including many new colored plates. These cannot be too highly praised, since they teach valuable points with the slightest effort on the part of the reader. The author approaches the subject in the same manner that the clinician approaches his study of a case, and the book has been accordingly divided into sections treating of the historical diagnosis, subjective diagnosis, objective diagnosis, physical diagnosis, and laboratory diagnosis. The smaller and second part treats of special diagnosis, arranged in a manner similar to the textbooks on general medicine.

Bacteriology of Milk. By Harold Swithinbank of the Bacteriological Research Laboratory, Denham, and George Newman, M.D., F.R.S.E., D.P.H., Medical Officer of Health of the Metropolitan Borough of Finsbury, and formerly Demonstrator of Bacteriology in King's College, London. New York: E. P. Dutton & Co., 1903.

The authors have here treated this interesting subject most exhaustively and from every point of view. While questions of preventive medicine and of the control of the milk supply are still open to revision, and comparatively little is known of the relationship between disease in the cow and its transmission to man by means of milk, these questions are here considered in the light of all tho knowledge up to date. Many collateral problems are alse studied that may throw light upon the original questionf Thus investigations were made into the bacteriology o. the air of dairies, milk-shops, bakehouses, workshops, and the open air in town and country. The authors found no exact relationship to exist between percentage of CO_2 in the air and numbers of organisms, although, in a general way, where CO_2. was most largely present, organisms were most numerous. Fermentation in milk is carefully studied, and, in order to give a better understanding of the subject, the process of fermentation, as a whole, is considered. The authors divide this process into two chief kinds: (1) When the action is direct and the chemical changes involved in the process occur only in the presence of a cell, the ferment or cell being described as an *organized ferment;* (2) when the action is indirect and the changes are the result of the presence of a soluble material secreted by the cell, acting apart from the cell, this soluble substance being termed an *unorganized ferment* or *enzyme*. The organized ferments are yeasts, bacteria or vegetable cells allied to them; the enzymes are ferments found in the secretions of highly specialized cells in plants or animals and have their best illustrations in the digestive agents which bring about assimilation of pabulum in the human body. This function is performed in some cases by the enzyme combining with the substance on which it is acting, and then by decomposition yielding the "new" digested substance and regenerating the enzyme; in other cases the enzyme, by its own molecular movement, sets up molecular movement in the substance it is digesting, and thus changes its condition. This is only one example of the many interesting topics constantly being discussed in a way to throw light on the original proposition. Epidemics of various diseases that have been traced to milk are described at length with the methods of contamination. The control of the milk supply by private and public agencies is also exhaustively considered. The book will prove especially interesting to all who are interested in public health problems. The general make-up of the volume, and particularly the plates, are clear and attractive

Railway and Other Accidents with Relation to Injury and Disease of the Nervous System. A Book for Court Use. By Allan McLane Hamilton, M.D., F.R.C.S. New York: Wm. Wood & Co., 1904.

This book, we are told, is intended for lawyers as well as for physicians. In the first and second chapters the disease conditions, or the diseases commonly known as traumatic neurasthenia and hysteria, or traumatic neuroses, are considered under the name of "accident aboulia." The writer has no doubt of the psychic origin of accident aboulia. "The symptoms are those of inaction and disordered cerebration, which need not have a serious pathological explanation, . . . at times the symptoms resemble those of real disease." This would seem to mean that "accident aboulia" is not a real disease. Headache, which is such a conspicuous symptom in these cases, is considered to be dependent upon anæmia (p. 31), although hæmatological studies do not seem to substantiate this statement. "The deeper reflexes may be absent in hysterical hemiplegia," the author says, but the deeper reflexes include the knee-jerks and the ankle-jerks, and we venture to say that these are never absent in hysteria.

The third chapter is devoted to injuries of the cranium and its contents, concussion, compression, and fracture of the skull being briefly discussed. Infective meningeal and cerebral disease and epilepsy are also considered. The fourth chapter deals with traumatic insanity. The author ranks himself with those who believe that head injuries are not frequently the cause of insanity, "yet many irregular psychoses are undoubtedly traumatic." He uses the term "acute dementia," as synonymous with hebephrenia or "a form of the dementia præcox of Pick." In chapter 5 injuries of the vertebral column and its contents are considered, the symptomatology of cord lesions being discussed briefly. Dr. Hamilton has never met a case of spinal progressive muscular atrophy which could be attributed to trauma, but he accepts "the possibility of a locomotor ataxia which may very closely resemble the form universally supposed to be so distinct an entity." In chapter 6 peripheral nerve injuries are discussed. This contains a great amount of tabulated matter about the nerves and muscles, their relations and distribution, which requires close study to comprehend. The concluding chapters are devoted to "Examination and the Possibility of Error," "Prognosis in Relation to Verdict," and "Fraud." The book contains a glossary for the aid of the non-medical reader, for the lawyer for whose guidance, as the title implies, the work is largely intended.

Society Reports.

AMERICAN THERAPEUTIC SOCIETY.

Fifth Annual Meeting, Held in New York City, June 2, 3, and 4, 1904.

(Special Report to the MEDICAL RECORD.)

THE meeting was called to order by President Howard H. Barker of Washington. After prayer by Rev. Thomas C. Easton, D.D., Reynold W. Wilcox of New York delivered the address of welcome to the visiting members. D. Olin Leech of Washington responded in appropriate terms. After the regular order of business had been transacted, the president delivered his annual address.

Presidential Address.—Dr. H. H. BARKER of Washington, D. C., reviewed the progress of therapeutics during the last year He first pointed out obstacles to such progress, viz., the prevalence of nostrums and proprietary remedies, and their exploitation by the press and the profession. He entered a protest against this practice, and discussed the ethics of the use of patent and proprietary medicines. A second obstacle was the growing evil of quackery. Quacks have multiplied *pari passu* with the adoption of medical practice acts, and probably in consequence of them. Such acts have been so loosely drawn that they might be construed as merely prohibiting the use of drugs—or the courts have so construed them—showing thereby that they were alarmingly ignorant of the true meaning of the term practice of medicine. Several decisions were cited in support of this statement. Dr. Barker protested against such a construction of the law, and urged that all who claimed to treat disease in any way whatsoever should be required to comply with the spirit of the law. A united effort on the part of the profession would remove these obstacles by disseminating wholesome information among physicians, medical students, and the laity. The following method of procedure was suggested: "(1) Discourage the advertisement of patent and proprietary medicines in the medical journals by withdrawing support from such as persist in accepting them. (2) Change patent and copyright laws so as to deprive such preparations of the protection of the law. (3) Secure the adoption and enforcement of just and uniform medical practice acts, and see that the phraseology of such laws is in no way ambiguous." Dr. Barker next considered recent advances in the etiology, diagnosis, and treatment of tuberculosis. The paper concluded with a discussion of recent advances in treatment by antitoxic sera, and by organic extracts, particularly those derived from the suprarenal capsule.

Symposium on Recent Advances in Anæsthesia.—Dr. R. W. WILCOX of New York referred to the discovery of ether anæsthesia and its first public demonstration in 1846 by W. G. T. Morton. Until that day no discovery in therapeutics had stood out in bold relief; since then, the discovery of asepsis alone was of importance comparable to the boon given to the world by Morton. Asepsis was a necessary corollary of anæsthesia. After lauding the beneficent effects of anæsthesia, Dr. Wilcox suggested the following points for discussion: (1) Of what avail is the enormous number of facts ascertained concerning anæsthesia, if the future anæsthetist is not to receive a thorough instruction as to the principles deduced from these facts? (2) While the best preparation for anæsthesia is the selection of a competent anæsthetist, has not the consideration of the patient as a subject for anæsthesia received too little attention? (3) Is it not too frequently the case that deaths not apparently intimately associated with anæsthesia have been ascribed to other causes, when a more careful study would have developed a causal relationship? (4) Has not the widespread use of general anæsthesia resulted in a higher death rate than is inseparable from its employment? Under the last heading, Dr. Wilcox urged greater care of the patient. The operating room was no place for lectures upon either the patient or the operation. General anæsthesia was next considered, as regarded, first, individual anæsthetics, and then the various mixtures of ether, chloroform, alcohol, and ethyl chloride. Such mixtures were undesirable, as a rule, on account of the difference in volatility of the ingredients. The paper concluded with a consideration of the latest aspects of local anæsthesia.

Recent Experimental Work on Anæsthesia.—Dr. T. SOLLMANN of Cleveland, in an exhaustive paper, considered the theory of the action of volatile liquid anæsthetics; the histological changes caused by anæsthetics; the dosage of chloroform and the effects of this drug on the heart and vasomotor system; treatment of the accidents of anæsthesia; operations in the excitement stage of ether, and various other topics.

General Advances in Anæsthesia.—Dr. M. F. THOMPSON of Washington, D. C., lauded the beneficence of anæsthesia, drawing a vivid picture of the sufferings of the patient without anæsthesia, and comparing early operations with the painless, deliberate, and thorough operations of to-day. After dealing with the subject historically, Dr. Thompson compared the anæsthetics in common use as to their advantages, disadvantages, indications, contraindications, etc. He spoke especially of nitrous oxide, and contrasted the early methods of making and transporting the gas with the present simply and efficient methods. Administration of the rubber hood was sometimes ineffective because of the admission of air through the moustache of the patient. He commended nitrous oxide-ether anæsthesia in the hands of experienced anæsthetists, but under ordinary circumstances preferred one anæsthetic or the other. Chloroform was next considered: its advantages, disadvantages, method of administration, evil effects, indications, contraindications, etc.; also the use of anæsthetics in labor, particularly chloroform. The paper concluded with a consideration of ethyl chloride as a local and general anæsthetic.

Recent Advances in Local Anæsthesia.—Dr. E. J. KEIPE of Buffalo, N. Y., began with a discussion of the method of action of local anæsthetics. Pressure anæsthesia induced by artificial œdema, as seen in massive infiltration, either alone or with pressure, offered gratifying results. Cocaine and eucaine still held first place as local anæsthetics. Other agents were open to the objection that they were either decidedly toxic, were not sufficiently penetrating, or were too irritating. After speaking of the strong solutions of cocaine formerly deemed necessary, Dr. Keipe noted the gradual diminution in the strength of solution employed down to that used by Schleich. The latest suggestion was that absolute anæsthesia could be secured for certain operations by injections of sterile water alone. In conclusion the author discussed the advantages of combining suprarenal extract with local anæsthetics.

Local Anæsthesia by Cataphoresis and by Pressure.—Dr. W. J. MORTON of New York suggested the term "electric medicamental diffusion," inasmuch as medicaments might, by electric pressure or voltage, be made to enter the sound skin or mucous membrane not only at the cathode but also at the anode of a battery. The subject was first treated historically. Little was really accomplished until the advent of cocaine; since 1886 the method had made rapid strides, and it could now be used efficiently for minor operations and major operations also, if desired. The addition of guaiacol or carbolic acid to the cocaine was an important step, diminishing the time of administration and the amount of current required. Dr. Morton had devised a new form of cataphoric electrode of metal, perforated with drill-holes in order to form honeycomb-like recesses for the fluid, thus providing a continual feed to the blotting-paper intervening between the skin and the metal. After discussing the physical basis for the method, the writer

illustrated the technique and cited an instance in which a nævus, 1 x 3 inches in area, was removed from the breast of a physician under this form of anæsthesia without any pain, the dissections extending to the depth of over an inch. Pressure anæsthesia was produced by forcing anæsthetizing solutions into the tissues by the pressure of vapors or gases, or by mechanical pressure. The method was devised by the speaker, and had become well-nigh universal, he said, in dental practice. A pledget of absorbent cotton, saturated with the anæsthetizing solution, was placed in the cavity of a tooth and closely sealed in with a soft rubber stopping; in a few minutes perfect anæsthesia was produced, so that the operator could excavate or even extract the nerve painlessly. It would seem that the evaporation of the ether forced the anæsthetic into the sensitive tissue of the tooth cavity.

Sterile Water Anæsthesia in the Treatment of Rectal Diseases.—Dr. Samuel G. Gant of New York described his method and illustrated it by a painless operation for prolapsus ani. He began experiments with sterile water in 1901. Recently the technique had been so improved that he used it to the exclusion of general and medicinal local anæsthetics in practically all but capital operations. He had employed it with gratifying results in several hundred operations, particularly about the rectum and lower bowel. The advantages of the method were: "(1) Effective local anæsthesia is easily and quickly obtained, thus saving the patient the annoyance and expense of hospital treatment under general anæsthesia. (2) The anæsthesia is produced instantly, and the operator can work quickly and treat the patient in the office. (3) Absence of complications and sequelæ. (4) Less pain and bleeding than when medicinal anæsthetics are used. (5) It eliminates the danger to life through complications which may follow general anæsthetics, as also the pain and hemorrhage due to straining and vomiting after general anæsthesia. (6) The only requirements are a hypodermic syringe, a suitable needle, and boiled water. (7) The radical treatment of hemorrhoids can be so easily carried out by the physician in his office, with so little danger and inconvenience to the patient, that it should relegate to oblivion the much vaunted injection treatment, which is so dangerous and uncertain." In conclusion, the paper dealt with the indications and contraindications of the method.

The Medical Treatment of Appendicitis.—Dr. A. J. Hall of Washington, D. C., believed that so many cases recover without surgical interference that therapeutics had not received the credit to which it was entitled. Appendicitis might be treated medically with a fair proportion of as good results as those obtained by the surgeon, the proportion of recoveries being so large that the physician could safely count upon successfully carrying his patient through the first and second acute attacks. The proposition to operate should be considered in the interval between the second and prospective third attacks. He presented statistics in favor of this view. This included every variety, from the mild "catarrhal" to the severest "pus" cases. His treatment was as follows: Rest in bed; hot poultices to the abdomen; liquid diet, mainly milk, 4 to 6 oz. daily; internally, the arsenite of copper and creosote; no purgatives nor opiates. His conclusions were that (1) the tendency in appendicitis was toward recovery; (2) all acute cases should be treated medically until, after mature deliberation, it was shown that operation offered a better prospect for recovery; (3) in recurrent cases operation should be advised in the interval after recovery from the second attack.

Dr. O. T. Osborne of New Haven spoke from a medical standpoint, but believed that one should always consider appendicitis a surgical disease. It might be necessary to consider operation at the very first attack. One could never tell from the severity of the symptoms the extent of the abdominal lesions, and anything but a little "flare-up" should be considered by surgeon and physician together. He reviewed the symptoms which, in his opinion, would call for an operation.

Dr. Leonard Weber of New York agreed with Dr. Osborne. Medical treatment did not cure appendicitis; the patients might get well, but there was always a probability of recurrence. He discussed the indications for operation. The question as to the best time for operating must be answered according to the merits of each case. He did not hesitate when there was much pain and swelling to give a small hypodermic of morphine.

Dr. D. Olin Leech of Washington, D. C., said that appendicitis was a surgical disease, and should be so treated. He did not believe that a case was ever cured by medicine alone, and the physician who temporized, and treated the patient by this means alone, was liable to make a serious mistake. The patient with appendicitis was like a man with a stick of dynamite in his pocket, one could never tell when there would be an explosion.

Dr. Carl Beck of New York spoke of the treachery and uncertainty of appendicitis as a distinguishing feature. One could not tell from the symptoms the severity of the abdominal lesions, and mild cases often suddenly became grave Some patients recovered without operation, but how was one to tell which would recover and which would die? No case was really mild, in view of this uncertainty, and one should choose the lesser of two evils and operate early.

The Need of Revising Our Ideas of Stimulation.—Dr. E. H. Long of Buffalo said that in view of the more exact knowledge of the action of drugs upon the system which obtains to-day, we could not employ the term stimulation as meaning always a definite and invariable kind of influence or phenomenon. Several factors related to this proposition: (1) a confusion of terms; physiological action and therapeutic effect were often confused; (2) a difference of view-point, *e.g.* that of the pharmacologist and clinician; (3) the factor of inhibition. He suggested the following classification of stimulants: (1) Agents that increase the irritability of nerve centers, or the conductivity of nerve fibers, thus increasing the potential of function, *e.g.* strychnine. (2) Agents that determine a more rapid or more powerful discharge of energy in the activity of a function, thus converting potential into kinetic energy, *e.g.* members of the digitalis group. (3) Agents that depress the nerves or nerve centers which exercise a restraining or inhibitory influence over an organ, thus allowing greater freedom of activity in its function, *e.g.* glonoin. A stimulant might be defined as any agent that increased temporarily the efficiency of a function by improving its innervation or increasing the activity of the organ or by lessening the restraint upon its action.

The Treatment of Chronic Colitis.—Dr. Jesse Shoup of Washington, D. C., after referring briefly to etiology and symptomatology, stated that he never saw a case of chronic colitis in which gastroptosis or enteroptosis was not present. Such defects should be remedied at the outset. He outlined the treatment as follows: "(1) Treat the attack of pain which precedes the passage of mucus by a hypodermic of morphine with atropine, and promote thorough evacuation of the bowels by giving large doses of castor oil by the mouth, and high enemata of oils or alkaline solutions. (2) Prescribe a carefully selected diet to suit the individual case, after a chemical examination of the stomach contents has been made. (3) Assist digestion, and allay fermentation. (4) Keep the bowels open by oils given by the mouth (the oil acts both as laxative and lubricant). (5) Apply a suitable support to overcome any ptosis of the abdominal organs (6) Treat locally by astringent enemata and oils. (7) Secure rest in the recumbent position, and where practical, change to the air of mountain or seashore."

The Etiology and Treatment of Arteriosclerosis.—Dr. O. T. Osborne of New Haven, after stating that a modification in the quality of the blood or a change in blood

pressure played an important part in all of the causes that had been assigned for generalized arteriosclerosis, emphasized the importance of a disturbance in the function of the ductless glands as the prime factor in the production of the disease. The gradual sclerosis which came on as age advanced was due to a natural increase in arterial tension and blood pressure, and this in turn he believed to be due largely to a modification in the function of the ductless glands. After discussing the function of each of these glands, he concluded that the thyroid furnished vasodilator material, and the suprarenals vasoconstrictor material, and any marked change in blood pressure, in the absence of drug stimulation, must be due to diminution of thyroid secretion or increase of suprarenal secretion, or both. After the age of fifty the thyroid secretion gradually diminished, the blood pressure gradually rose, and there was an increasing tendency to sclerosis, until, in old age, when the thyroid had atrophied and blood tension was at its highest, arteriosclerosis was in evidence. The only other hypothesis must be the possibility of some irritant in the blood which either stimulated the vasomoter centers to keep up peripheral contraction, or finally caused a slow-going endarteritis with resulting arteriosclerosis. So long as there was an adequate compensatory hypertrophy and an increased power of propulsion of the blood, the individual had no trouble; but when this muscular power was upset in any way, significant symptoms arose, which, if recognized as indicating a coming arteriosclerosis, would enable the physician so to treat his patient that the disease might be postponed for years. He should eat less, drink less, take regulated exercise to get more blood into his muscles and relieve the arteries, take regularly a period of business rest, and perhaps some proper medication. The patients could not, however, as a rule stand large doses of arterial depressors without complaining of malaise. The author referred to the following accepted causes of arteriosclerosis: Nervous strain, with its resulting increase of blood pressure, due to pressure of business, exciting diversions, etc. Overeating, which produced arteriosclerosis by causing the absorption of toxins from imperfectly digested food, thus irritating the blood-vessels to contract and causing endarteritis, or possibly, the toxins might irritate the suprarenals to increased action. Alcoholism tended to cause atrophy of the thyroid with a resulting diminution of vasodilator secretion. Severe and prolonged muscular exercise tended to produce increased arterial pressure, and hence, arteriosclerosis. Syphilis could not be declared a cause of arteriosclerosis until we had separated its results from those of the chronic action of mercury. The alteratives acted by modifying the secretions of the ductless glands; the metals interfered with the action of the thyroid; the prolonged administration of mercury caused atrophy of the thyroid with increased arterial tension, and connective-tissue formations. Lead, in chronic poisoning, acted in the same way. In renal insufficiency the blood tension because relatively high, and there was a tendency to arteriosclerosis. The gouty diathesis was also attended with increased arterial tension. He suggested, as a cause of gout, a disturbance of suprarenal secretion, perhaps an increase of it. Treatment, to be successful, must aim to diminish the high blood pressure. This could well be accomplished by thyroid extract or the iodides in small doses, if we believed that the thyroid secretion was diminished. Diet, exercise, rest, and other hygienic factors should receive careful attention, and directions should be given for the avoidance of causes tending to produce high arterial tension. The paper closed with the suggestion that it was possible that in the future one of the suprarenals might be removed, or its artery tied for the relief of gout or arteriosclerosis.

Dr. J. N. Hall of Denver spoke of severe muscular exercise as an etiological factor. He cited the case of a man who had to walk seven hundred miles over mountains, with a pack on his back; he did it in twenty days, apparently without harm. But at the age of forty-one, six years later, he had a marked arteriosclerosis with mitral symptoms. He commended aconite as the best remedy in most cases.

Dr. L. Weber of New York spoke particularly of arteriosclerosis of the heart and kidneys. He drew a distinction between the affection in old age and that which came on earlier in life: the latter was abnormal and dangerous, inasmuch as it was associated with organic changes. Syphilis, gout, and alcoholism were the most important causes of premature arteriosclerosis. A syphilitic was more liable than others to have arteriosclerosis. Moderate doses of iodide give the best result; it acted as a poison to the mushroom growth of cell infiltration which was at the bottom of the syphilitic endarteritis. Gouty cases were benefited by sodium iodide. Patients with interstitial nephritis returning from watering-places where they had been drinking an excess of water did badly; the excess was not beneficial, but harmful. Finally, no matter how much work a man was forced to do, unless some underlying disorder was present he was not likely to have arteriosclerosis, as if this factor was present.

Symposium, the Combat with Infection. Infection and Immunity.—Dr. T. E. Satterthwaite of New York first considered the subject historically, giving credit to the discoverers whose names figured prominently in the domain of bacteriology. He then discussed the germs which caused the different infectious diseases, and classified them as bacteria, fungi, and protozoa. After speaking of the products of germ growth, and contagion as contrasted with infection, the paper dealt with the subject of human as compared with animal infection. The behavior of an animal toward an infection varied according to the species, the individual, and the circumstances. Hence there was liable to be a wide difference between the human disease and the experimental disease of animals as to both symptoms and lesions. As an example he mentioned tuberculosis. The lesions were very unlike in men and animals. In 1896 Theobald Smith noted also a difference between the bacilli. The writer next dealt with immunity, natural, acquired, and inherited. He recognized two varieties of the acquired form, active and passive. Active immunity was such as was caused by one attack of an infectious disease, small doses of virulent cultures, etc. Passive immunity was a condition such as that produced by serum therapy, the individual inoculated with the antitoxin sharing the immunity passively with the animal from which the antitoxin was drawn. Mixed infection was next considered, and then curative sera and their preparation and standardization, and finally agglutination tests. The paper closed with a discussion of the various theories of immunity: (1) the exhaustion theory; (2) the retention theory; (3) the phagocytic theory; (4) the humoral theory; (5) the cellulohumoral theory, which sought to unite the theories of the phagocytic and humoral schools. Ehrlich's side-chain theory was considered, the author concluding that while it had met with opposition, and would doubtless be modified to meet reasonable objections, it was convenient for us to accept it provisionally as a good working hypothesis that would be helpful in discovering the principles that governed immunity, whatever they might be.

Antisepsis in Internal Medicine.—Dr. J. N. Hall of Denver spoke of the advances of the last decade. They had been more marked in surgery than in medicine. After discussing the efficacy of the various antitoxins, the author considered antisepsis in digestive diseases. He emphasized the fact that the hydrochloric acid of the gastric juice was the natural antiseptic at the gateway to the system, minimizing the danger of infection. The reported hyperacidity of the digestive fluids of carion-eating birds was significant in this connection. The administration of hydrochloric acid in typhoid fever was based upon two foundations: it supplied a digestive ingredient lessened by the fever, and it tended to prevent the growth of organisms

in the intestines of the patient weakened by fever. Intestinal antisepsis was next considered. Failure to obtain the results once confidently expected in typhoid fever might have been foreseen. We might be able to modify the symptoms arising from the absorption of toxins, but the bacilli established in the spleen, mesenteric glands, or even the meninges, must also be dealt with; we could scarcely cure a typhoid meningitis by the exhibition of an intestinal antiseptic. After a caution as to the abuse of remedies of this class, the author turned to antisepsis of the genitourinary tract. Here success had been more marked. Typhoid and colon bacilli in the urine had been made to disappear rapidly by the use of internal remedies. There was good ground for hope that we might yet find an intestinal antiseptic as efficacious as some of our urinary antiseptics. Turning to respiratory disorders, the author considered tuberculosis at length. Creosote and its congeners acted by rendering the soil unsuitable as a culture ground rather than directly as germicides. He found antistreptococcus serum disappointing in cases of mixed infection. In a case of "streptococcus consumption," however, it promptly caused the disappearance of the germs. Intravenous injections of dilute formaldehyde solution were very painful and produced no obvious good results. The paper concluded with a consideration of the efficacy of certain silver salts as internal antiseptics.

Protective Inoculation.—Dr. G. F. Butler of Alma, Mich., said that in its development, inoculation had followed the lines of folk-lore in which human sacrifice became modified into animal before passing into the mere symbol. Through this line of evolution all therapeutics and pathology had passed in the employment of animals to determine certain effects on human beings. One element of error existed, particularly in case of protective inoculations. the difference between man and animals were ignored, while in the cultivation of an alleged microbe Koch's law was ignored. The microbe or protozoon found with a disease was regarded as the cause, and was cultivated to produce a serum. A given hypothesis, however, to be accepted must not only explain all of the facts, but must exclude all other explanations. Hence this requirement was set at defiance, and the possible was but too often taken for the real. Microbes and protozoa were not the same biologically or nosologically. The history of smallpox protective inoculations demonstrated the line of research to be followed in the evolution of future systems of inoculation. In studying protective inoculation, comparative medicine first demanded thought. The writer called attention to the difference between the manifestations of disease and bacteriological effects in different classes of organisms, *e.g.* animals and man. He discussed Ehrlich's theory and the subject of mixed infection. Tuberculosis was caused by the tubercle bacillus, the pneumococcus, the Pfeiffer-Canon bacillus, and pus cocci. Furthermore, tuberculosis of cattle differed from that of man. To meet all of these factors by inoculation was a difficult problem. He concludes: "The problem of protective inoculation, therefore, implies a study of comparative medicine with the variation between man and animal taken into account, but also, a careful study of the hygiene and prophylaxis of the animal employed and of the human being, before, during, and after inoculation."

Dr. E. H. Long commended the papers as being interesting and instructive. For the general practitioner as much could be gained by the use of intestinal antiseptics as from gastric examination and treatment based upon it. Fermentation, due to factors hindering digestion, was the great difficulty rather than deficient digestive power. Intestinal antiseptics could only modify the severity of typhoid fever, and according to his experience bismuth, creosote, naphtol, and salol were most reliable. Conclusions concerning the efficacy of antistreptococcus and antipneumococcus serum were as yet immature and not final. He mentioned two cases in which these serums were given for scarlet fever and pneumonia respectively with the result that they saved the patients lives.

Dr. O. T. Osborne commended the use of hydrochloric acid in typhoid fever. Formerly he gave a diet without salt; this was a mistake, as it produced almost an absence of the acid in the stomach. He also commended the use of intestinal antiseptics. Salol should not be given in large doses, or long, without daily examinations of the urine for albumin, and if this were found, the salol should be discontinued. Acute rheumatism he believes to be an infection starting from the bowel; hence the advantage of the salicylates. Arsenic gave good results in pernicious anæmia, but its administration should not be pushed either in this affection, or in leukæmia. The evil effects of creosote upon the digestive organs often more than off-set its beneficial effects.

Dr. T. E. Satterthwaite expressed pleasure that the use of intestinal antiseptics had been endorsed by the speakers. He had often been obliged to defend their administration. He advocated bismuth and hydrochloric acid in typhoid fever. He used them first in a great epidemic and got better results than from any other method of treatment. The value of antistreptococcus serum was still under consideration, and he was glad to hear that it had met with some success.

Arthritis Deformans and Its Treatment.—Dr. L. Kolipinski of Washington, D. C., after speaking briefly of etiology and symptoms, recommended treatment under the following headings: (1) relief from pain; (2) correction of stiffness, rigidity, and contractures; (3) increase of the muscular strength; (4) cure of the anæmia, (5) increase, when necessary, of the body weight; (6) treatment of the heart. To accomplish these ends three agencies were necessary, no one or two of which would suffice: for the pain, anæmia, weak pulse, and malnutrition, arsenic; for stiffness, contracture, and muscular atrophy, voluntary exercise; for the weakness, loss of weight, and pain, improvement of the nutrition by increase and selection of the food supply. The arsenic must be used for a year or more. It might be given in the form of Fowler's solution, the arsenite of zinc, or hypodermic injections of the acid, according to the variety and indications. He lay special stress upon the value of voluntary exercise and dietetic treatment. The diet should be liberal, varied, and mixed.

The meeting closed with a symposium upon "Recent Advances in Special Therapeutics." The following members read papers: Drs. D. B. St. John Roosa of New York, Carl Beck of New York, Solomon Solis Cohen of Philadelphia, W. J. Morton of New York, Russell A. Hibbs of New York, E. B. Bronson of New York, Charles H. Knight of New York, James Pederson of New York, and Noble P. Barnes of Washington.

Officers.—The following officers were selected for the coming year: *President*, Oliver T. Osborne of New Haven; *Vice-Presidents*, J. N. Hall of Denver, Carl Beck of New York, and John V. Shoemaker of Philadelphia; *Secretary*, Noble P. Barnes of Washington, D. C.; *Treasurer*, John S. McLain of Washington, D. C.; *Recorder*, William M. Sprigg of Washington, D. C.; *Curator*, George C. Ober of Washington, D. C.

Light Treatment after Sensibilization.—Dreyer says that we can render sensitive yellow and green luminous rays in bacteria and infusoria by adding a little erythrosine to their nutrium medium. In lupus this application permits a deeper action and with more prompt effect than the ordinary method of treatment. He employs solution of one to one thousand of Grubler's erythrosine in physiological salt solution. Subcutaneous injections are made from half a gram to a gram, and exposure to light is made four to eight hours after the injection.—*Dermatologische Zeitschrift.*

NEW YORK ACADEMY OF MEDICINE.

SECTION ON MEDICINE.

Stated Meeting, Held May 17, 1904.

DR. CHARLES H. LEWIS, CHAIRMAN.

Notes on Some Uncommon Forms of Nervous Diseases.—Dr. L. PIERCE CLARK read this paper (see page 121).

The Modern Tuberculosis Dispensary, with a Report from the Health Department.—Dr. S. A. KNOPF read this paper (see page 125).

Dispensary Treatment of Tuberculosis at Gouverneur Hospital.—Dr. STELLA J. BRADFORD read this paper. She stated that prior to October, 1903, there had been no separate clinic for the treatment of tuberculosis under any city jurisdiction and she reviewed what had been done at that time. In October Dr. Seamore asked that a separate clinic be formed and in January appointments were made. This separate clinic had now been in existence for seven months, and Dr. Bradford reported observations and the results obtained from systematic treatment of these patients, numbering ninety-two. Only one room was available for this work, and unfortunately there were as many as ten or fifteen people in this room at once. Of this number, diagnosed as tuberculous, sixty were males and thirty-two females. The range of ages was large but the largest number was between the fourth and fifth decades. Regarding nationality, Americans were only second to the Russians. The histories given by these patients showed the principal symptom to be cough in 77, weakness in 35, pain in the chest in 16, hemorrhages in 10, etc. The symptoms were, as a rule, fairly classical. The sputa in 54 per cent. gave positive diagnosis. The treatment was a very simple one. Full histories were taken on blanks furnished them and a thorough physical examination, including measurements, was made. Hygienic treatment was emphasized and methods for prophylaxis were taught. For a stimulant and tonic strychnine was depended upon. Heroin was relied upon to control the cough; it was given in aqueous solution, 1-24th of a grain four times a day, and the dose was increased according to indications. Of the 92 cases 49 presented themselves with fair regularity; 8 were in the hospital, 2 in the country, and 1 under the care of a private doctor. The remaining 32 were referred to hospitals, but there was no way of learning whether they went or not. Twenty-six gained in weight averaging four pounds; 13 lost weight averaging $2\frac{1}{4}$ pounds. Many difficulties were experienced in treating these cases. They were not able to provide milk or eggs and they had no specially trained nurses. Dr. Bradford referred to the great importance of teaching children the dangers of the disease. Work should be provided for those who were able and willing to work.

Dispensary Treatment of Tuberculosis at Vanderbilt Clinic.—Dr. LINSEY R. WILLIAMS said that, at this clinic, they dealt almost entirely with advanced cases of tuberculosis and among the very poor and a great many difficulties were encountered in obtaining cures. This special work, he said, was begun by Dr. Miller in 1893. An important part of the treatment consisted in gaining the confidence of the patients; they were then informed what the disease was, the value of rest, ventilation, etc., and its dangers, and how avoided. Records were made of the temperature, pulse, respirations, weight, and the amount of food taken and work done. District nursing was made possible by donations from Mrs. Vanderbilt. A nurse visited the homes of those afflicted with the disease, left slips, etc. As many as 225 to 250 calls a month had been made on 125 patients. Beginning May 1, 118 people a week were visited. Practically no incipient cases were encountered. Through the kindness of Dr. James a small fund was obtained with which to provide printed slips and sputum boxes. No milk or eggs could be supplied them, but the Charity Organization Society aided them greatly in their work. The Board of Health examined the sputa and gave fumigations. The work was as yet small, but they reached a great many people.

Dispensary Treatment of Tuberculosis at Bellevue Hospital.—Dr. JAMES A. MILLER said that this work was opened in December, 1903, and he considered the work done under five headings as follows:

1. Careful medical attention in special clinic by experienced physicians was given. These patients were sent into a special room where the temperature, pulse, respirations, chest measurements and weight with the patient stripped to the waist were taken. If they were found to be afflicted with tuberculosis the name and address were taken and given the nurse for visitation. The sputum was sent to the Health Board for examination. Printed circulars and other instruction was given them and the diet dwelt upon. Milk and eggs were provided if too poor to buy them, and but little attention was paid to any medication. Pocket sputum box was given the patient and the patient was then requested to return once a week.

2. A thorough investigation of the home conditions by a special nurse was made. At Bellevue there were two such nurses. After they had made thorough inspections of the homes a report was made. An attempt was made to arrange the whole domestic economy of the home and practical disinfection was demonstrated.

3. Proper education of the patient and his family in regard to hygiene and the prevention of the spread of infection was attempted and circulars of information given.

4. A study of the social and economic conditions as obtained in each case was made, and upon this was based the method of management of the case. They kept in close touch with sanatoria and hospitals and charitable organizations, such as the Charity Organization Society, etc. Milk and eggs were provided from the hospital store. Tents and cottages had been placed upon the hospital grounds.

5. An opportunity for scientific investigation and clinical study was thus afforded for doctors and students.

During seven months they had had 166 cases; the small number was due to the fact that part of the time the out-door department was closed. About 40 new cases a month came in. These patients made 667 visits to the clinic; the nurses made 411 visits to their homes. Of this number, 166, 28 were not found. Sixty-seven cases had been sent to the hospital. May 1 there were 71 cases under observation. In 122 instances help was given, the help coming sometimes from different sources. A total of 2544 quarts of milk was given away at a cost of about $127 and 495 dozen eggs at a cost of $108, a total cost for milk and eggs of $235.

Dispensary Treatment of Tuberculosis at the Throat, Nose, and Lung Hospital.—Dr. J. L. BARTON said that this special department was organized in 1891 and incorporated in 1893, and this clinic for the treatment of tuberculosis was rather unique in that it used the cabinet and gave Koch's tuberculin; otherwise it differed but little from other clinics of same nature. The experience of ten years in this work was encouraging and, in a large number of cases, the disease was arrested. The result of their work warranted him in giving the following conclusions:

(1) Tuberculosis, as a rule, was contracted by those who were suffering from malnutrition; (2) each case *sui generis* was treated without any idea of attaining the Utopian; (3) any clinical division of the disease seemed unimportant; (4) patients in the incipient stages and those whose vitality was not exhausted not only improved but got well; (5) a very large proportion of those afflicted with the disease need not leave their homes or places of business; (6) every form of treatment was of value when used as an adjunct; (7) well

organized clinics with trained district nurses will do more to eradicate the disease than can be done in any other way; (8) hospitals should be provided for those having no means; advanced cases were likely to be centers of infection; (9) the greatest cause of the spread of tuberculosis was malnutrition; (10) an optimistic attitude on the part of the physician was necessary to success; (11) people should be taught how to live, including self-control.

Use of the X-ray in the New York Health Department.—Dr. C. T. Graham Rogers contributed this paper to the symposium. He said that a method for detecting tuberculosis in its early stages was much needed, and efforts in this direction should not be condemned. Before undertaking the study of diseased pulmonary conditions fluoroscopical charts of normal chests should be carefully studied. The doctor then described his technique. The right apex did not appear as distinctly as the left. The action of the diaphragm was very well marked. In incipient stages of the disease, with slight infiltration, it appeared merely as a haze and, as the disease progressed, the haze changed to a shadow showing consolidation. Many cases showed a thickened pleura. Limitation of cavities could be shown. In cases of miliary tuberculosis the appearance was mottled. Certain restrictions to the movements of the diaphragm should lead to very careful examinations. The physical examinations of the chest were always made with special reference to the fluoroscopical markings. Good effects were to be had not only from the influence of the rays but also from the inhalation of ozone. Among the seventy-one cases, thirty had been *x*-rayed, each patient coming three times a week; this would relieve the pain and, in some cases, the cough and the patients were helped also, because they knew that something was being done for them besides the giving of medicines internally. As a result of his observations he stated that the *x*-ray may aid in the recognition of the disease in its early stages; that the development and inhalation of ozone was a factor in the treatment; that the psychic effect was of great value.

Dr. John H. Huddleston said that the oldest line of work in the treatment of the ambulatory cases of tuberculosis was shown in New York City dispensaries, and to-day those afflicted with the disease were better off in the city, under the care of competent physicians, than if they were sent away to an excellent climate without the trained direction of competent physicians. He said that few realized how very young this work was, dating as it did to 1895 in one instance, and to 1904; October, 1903; early part of 1903; December, 1903 and 1904, the figures given by the readers of the papers. More than 5,000 consumptives were supposed to be under control, and these people were being properly treated and instructed, being made centers of instruction rather than centers of infection. The disease was a chronic one, and the successful treatment of it depended largely upon the personality of the physician, and just so much as the physician can command obedience just so much could the patients be helped. He emphasized the fact that what is *told* the patient is remembered and not what is written. Nurses should be provided wherever possible to see that the physicians instructions were being faithfully carried out.

Dr. George William Beach of Binghamton said that similar work had just been started in Binghamton and as yet nothing had been accomplished In his city, although there were no tenements, the conditions were just as bad, for frequently ten or more people slept in the same room in the cottages.

Dr. John L. Barton said that he never sent patients away now unless they wished to go, because they could be made to do just as well here, if not better. He also did not place much importance upon stomach medication.

Dr. J. Finley Bell of Englewood said that frequently the good result of a sojourn in the Adirondacks was lost, because too much dependence was placed upon living in a certain locality; there was too much insistence upon climatic conditions to the neglect of other features in the treatment of these sufferers.

Dr. S. A. Knopf, in closing the discussion, said that while Dr. Rogers had read an admirable paper on the use of the *x*-rays as a means of early diagnosis and as a therapeutic adjuvant in certain cases, he had failed to speak of the *x*-rays as a valuable means to make a prognosis. Dr. Knopf thought that a large area of perfectly transparent pulmonary tissue, revealed by the fluoroscope, was a justification for making a favorable prognosis, particularly when there were other concomitant favorable symptoms. He thought the fluoroscope of greatest diagnostic value in cases in which the tuberculous deposits were disseminated here and there through the lungs, and too small to be discovered by the ordinary physical means of examination. In interpreting an ordinary shadow one should always think of the possibility of a thickened pleura, an old pneumonia, or new growths of other than tuberculous character (carcinoma, echinococcus cysts, etc.).

The remarks made by the various speakers about the advisability of treating all patients in New York City who do not themselves insist upon going away, Dr. Knopf said he wished to endorse with some qualifications. He had always maintained that the majority of patients, who are the poor and the laboring classes, should be treated in the same or nearly the same climate in which they would have to live and labor after their restoration to health. This, however, did not mean that we should be nihilists in regard to climatotherapy. Climate and altitude were certainly valuable adjuvants to the hygienic and dietetic treatment of consumptives, and there was no doubt that the majority of patients did better at an altitude of from 300 to 1,500 feet, or even more, when under proper medical supervision. Quiet, peaceful, natural surroundings, a great deal of sunshine, and a dust-free atmosphere were conditions which were not easily obtained in the city of New York—at least, not for the majority of patients. While great climatic changes were not necessary, Dr. Knopf firmly believed that sanatoria situated at not too great a distance from large centers of population, but in particularly healthful country districts, would give better results than when located in the city. The relative proximity to the former home of the patient would exclude nostalgia, which was so often a depressing factor when patients went to far-off health resorts.

Conference of State and Provincial Boards of Health.

The nineteenth annual conference of State and Provincial Boards of Health of North America was held at the New Willard Hotel, Washington, D. C., June 3 and 4, 1904. After the president of the conference, Dr. J. N. Hurty of Indianapolis, had delivered his annual address, the secretary, Dr. Gardner T. Swarts of Providence, R. I., presented his report, and also the report of the treasurer, in the absence of the latter. Dr. John S. Fulton of Baltimore, Md., submitted the report of the committee appointed to investigate and report as to an approved disinfectant to be used by licensed embalmers when transporting bodies. The reports recommended the use of bichloride of mercury 1-1000, and formaldehyde ten-per-cent. solution, for use on the exterior of the body and wrappings. The report of the committee was adopted, and the committee continued for a further report at the next annual meeting.

The committee, which had under consideration the question of affiliation with the American Medical Association, presented its report through Dr. Henry D. Holton. For several reasons, the committee thought that the interests of the organization could be better subserved by retaining its own identity to the fullest extent. The

report was adopted. There was also considered a resolution which was presented at the Baltimore meeting last year, relative to legislation looking to the prevention of typhoid fever, caused by sewer contamination of oysters. Dr. Swarts reported considerable interest in the matter throughout the country, particularly in New Jersey and California. There was considerable discussion on this subject by Drs. Lee, Fulton, Mitchell, and Lindsley. It was stated that the infection took place after the oyster was removed from the salt water and put into fresh water ponds for the purpose of enlargement by absorption of the water. This water, often contaminated, caused the infection of the oyster. The resolution offered by Dr. J. A. Egan of Springfield, Ill., at the meeting in Baltimore, in 1903, to the effect that measures be taken by boards of health, boards of education, and school authorities to compel legislation looking to the examination of the eyes and ears of all school children, was considered in connection with a paper by Dr. Frank Allport of Chicago. As Dr. Allport was not present, the secretary read his paper.

Dr. C. E. Cooper of Denver, Col., introduced a resolution recommending the disinfection of railway cars and their contents by air pressure. The resolution was freely discussed, then referred to a committee to report at the next meeting of the conference.

Dr. Holton presented the report of the committee to consider the best means of controlling the spread of venereal diseases. The committee prepared a leaflet containing instructions for the patient, which it recommended should be widely distributed. The report of the committee was adopted. In connection with the same subject, Dr. F. C. Valentine of New York City read a carefully prepared paper on the dangers and spread of venereal diseases. On motion, the Committee on Veneral Diseases was continued with the request that everything possible be done to further the work.

A paper prepared by Mr. Henry Clay Weeks, secretary of the National Mosquito Extermination Society, Bayside, L. I., was read by L. O. Howard, Chief Entomologist U. S. Department of Agriculture. Dr. Carl L. Barnes of Chicago discussed disinfectants to be used by undertakers.

The officers elected for the ensuing year were: *President*, Dr. John S. Fulton, Baltimore, Md.; *Vice-President*, Dr. M. K. Foster, San Francisco, Cal.; *Treasurer*, Dr. J. A. Egan, Springfield, Ill.; *Secretary*, Dr. Gardner T. Swarts, Providence, R. I.

Pathological Society of Philadelphia.

At the annual conversational meeting, held April 28, Dr. Milton J. Rosenau, Director of the Hygienic Laboratory of the United States Public Health and Marine Hospital Service, delivered, by invitation, an address entitled "Some Studies in Yellow Fever." He first paid a deserved tribute to the genius of American investigation that is to be credited for the solution of one of the most important problems in the field of trophical medicine. It is true that the cause of yellow fever is as yet undiscovered, but its mode of transmission has been definitely and conclusively established, and as a result a successful means for preventing the dissemination of the disease has been devised and put into practical operation. Jenner has made his own monument in the discovery of vaccination as a preventive of smallpox, Pasteur his in the prevention and treatment of hydrophobia, and Reed and his colleagues theirs in the demonstration that yellow fever is conveyed by the stegomyia fasciata, and that transmission can be prevented by preventing access of this parasite. It was at first thought that the salivary glands of the mosquito played an important part in the transference of the virus of the disease, but it was later found that the œsophageal diverticulum constitutes the intermediating structure in this connection. The most careful microscopical examination and the most painstaking culture experiments failed to disclose any organism that could be considered as the cause of yellow fever. The myxococcidium stegomyiæ was found definitely not to hold this relation, and it was proved to be merely a yeast, of which innumerable varieties prevail in tropical climates. Interesting studies of the yeasts upon various fruits were made. Careful observations, the results of which accorded with those of others, showed that the period of incubation of yellow fever is between three and four days under ordinary conditions—that is, when infection takes place in the customary manner. This of course is a matter of the greatest importance in connection with the public health and the measures to be instituted to prevent the spread of the disease from the sick to the well. In cases of artificial inoculation, however, the period was extremely variable somewhat in accordance with the previous treatment and the mode of inoculation. It was less than two days when infected blood was injected directly into the veins and as long as twelve days when the inoculations were made into persons that had previously received injections of immunizing serum. The disease could be produced by means of serum obtained from the blood of infected persons by sedimentation and passed through a Pasteur-Chamberland filter B. That the bodies passing through such a filter are not necessarily ultramicroscopic was shown by the fact that carbon in the form of India ink passed through and the particles could be demonstrated microscopically. Comparative experiments with malarial blood showed that when inoculations were made with the serum of blood obtained at the height of the paroxysm and promptly defibrinated and filtered a single malarial paroxysm resulted, which it was thought might possibly be due to the malarial toxin. This result was obtained in a case of tertian fever, but failed to take place in a case of estivo-autumnal fever when the blood was obtained in the decline of the febrile paroxysm and the serum was permitted to separate slowly in the refrigerator. Two forms of albumin were found in cases of yellow fever examined from this point of view. The one was ordinary serum-albumin demonstrable with the usual tests and due to the fever and the general intoxication. The other was precipitable by ascetic acid, and was thought to be of cellular origin resulting from the alterations induced in the kidneys. It was again demonstrated that fomites had no influences whatever in the transmission of the disease. If sick and well were kept together, even in the most intimate contact, but the stegomyia was excluded, infection was never transmitted. It was found that a screen with 17 strands of wire and 16 meshes to the inch still permitted the passage of the mosquito, while a screen with 20 strands and 19 meshes prevented its passage. The insects could be made to bite and suck the blood of cadavers dead of yellow fever, but the infectivity of the blood under such circumstances was not marked and the danger of infection from such a source is considerable. Although the insects bite especially by day, they are capable of manifesting their activity by artificial light at night and also in the early morning. The best culicide was found to be sulphur. The stegomyia was shown to be a domestic insect, flourishing in small accumulations of water in yards and about dwellings, as in old tin cans or bottles or jars. Both males and female may live for three months or more.

Liverpool's Enterprise.—The enterprise of Liverpool is a pleasant thing to contemplate in these days of supposed national degeneration. Its School of Tropical Medicine is the most famous in the world; its ambulance system a model for all cities; its new university one of the most active and successful. Its latest development is the founding of the leading school of veterinary science in Great Britain, where the veterinary surgeon can obtain an education as complete as that of the medical student. This means not merely that disease amongst animals will be more successfully prevented than ever, but that highly trained veterinarians will be able to throw much new light upon human ailments.—*The Globe.*

Books Received.

While the MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

MEDICAL TUBERCULOSIS; ITS RATIONAL AND NATURAL CURE, ITS SEVERAL STAGES, AND ITS RELATIONSHIP TO CANCER. By R. B. SEARLE, L.R.C.P., M.R.C.S., L.S.A. 12mo, 40 pages. The Scientific Press, Ltd., London, England. Price, 1 shilling net.

DIAGNOSIS FROM THE EYE: A NEW ART OF DIAGNOSING WITH PERFECT CERTAINTY FROM THE IRIS OF THE EYE, THE NORMAL AND ABNORMAL CONDITIONS OF THE ORGANISM IN GENERAL, AND OF THE DIFFERENT ORGANS IN PARTICULAR. By HENRY EDWARD LANE, M.D. 8vo, 156 pages. Illustrated. Muslin. Kosmos Publishing Co., Chicago, Ill.

PROGRESSIVE MEDICINE. A Quarterly Digest of Advances, Discoveries and Improvements in the Medical and Surgical Sciences. Edited by Drs. HOBART AMORY HARE and H. R. M. LANDIS. Vol. 6, No. 2. By various authors. 8vo, 334 pages. Illustrated. Lea Bros. & Co., Philadelphia. Price, $6 per annum.

MODERN OPHTHALMOLOGY: A PRACTICAL TREATISE ON THE ANATOMY, PHYSIOLOGY, AND DISEASES OF THE EYE. By JAMES MOORES BALL, M.D. 8vo, 820 pages. Illustrated. Muslin. F. A. Davis Company, Philadelphia. Price, $7 net.

UNCONSCIOUS THERAPEUTICS: OR, THE PERSONALITY OF THE PHYSICIAN. By ALFRED T. SCHOFIELD, M.D., M.R.C.S. 8vo, 317 pages. Muslin. P. Blakiston's Son & Co., Philadelphia, Pa. Price, $1.50 net.

NEW YORK EYE AND EAR INFIRMARY REPORTS. 8vo, 100 pages. Illustrated. G. P. Putnam's Sons, New York. Price, $1.50.

DIGEST OF RESEARCHES BY LABORATORY WORKERS OF THE SMITH, KLINE & FRENCH COMPANY. Vol. 1. 8vo, 66 pages. Smith, Kline & French Co., Philadelphia.

ARTERIA UTERINA OVARICA: THE UTERO-OVARIAN ARTERY OF THE GENITAL VASCULAR CIRCLE. By BYRON ROBINSON, B.S., M.D. 8vo, 182 pages. Illustrated. Muslin. E. H. Colegrove, Chicago, Ill. Price, $1.

TRAITEMENT DE LA TUBERCULOSE PULMONAIRE PAR LA MÉDICATION INTRA-TRACHEALE. Par Dr. HENRI MENDEL. Introduction by Professor BRISSAUD. Deuxieme Edition. 8vo, 146 pages, illustrated. F. R. de Rudeval, Paris, France. Price, 5 fr.

TRAITÉ DE MÉDECINE. By various authors Volume IX, second edition. 4to, 1092 pages, illustrated. Masson & Cie, Paris. Price, 18 fr.

UEBER IMMUNITÄT BEI SYPHILIS NEBST BEMERKUNGEN ÜBER DIAGNOSTIK UND SEROTHERAPIE DER SYPHILIS. Von Dr. FRANZ NAGELSCHMIDT. 8vo, 70 pages. August Hirschwald, Berlin.

UEBER DEN SCHLUCKMECHANISMUS. Von Professor Dr. JULIUS SCHREIBER. 8vo, illustrated, 91 pages. August Hirschwald, Berlin.

LEHRBUCH DER SPECIELLEN CHIRURGIE FÜR AERTZE UND STUDIRENDE. Von Dr. FRANZ KOENIG. Achte Auflage. Bände 1 and 2. 8vo, illustrated, paper. Band 1, 803 pages. Band 2, 941 pages. August Hirschwald, Berlin.

SEVENTEENTH ANNUAL REPORT OF THE STATE BOARD OF HEALTH OF THE STATE OF OHIO year ending December 31, 1902. 8vo, 508 pages.

LES ACTUALITES MÉDICALES. CHIRURGIE NERVEUSE D'URGENCE. Par le Dr. A. CHIPAULT. 12mo, 96 pages. J. B. Baillière & Fils, Paris, France. Price 1 fr. 50.

THE DEVELOPMENT OF THE HUMAN BODY: A MANUAL OF HUMAN EMBRYOLOGY. By J. PLAYFAIR MCMURRICH, A.M., Ph.D. 8vo, 527 pages, illustrated, muslin. P. Blakiston's Son & Co., Philadelphia.

A SYSTEM OF PRACTICAL SURGERY. By Drs. E. VON BERGMANN, P. VON BRUNS, and J. VON MIKULICZ. Volume 3, SURGERY OF THE EXTREMITIES. Translated and Edited by WILLIAM T. BULL, M.D., and JOHN B. SOLLEY, M.D. 8vo, 918 pages, illustrated, muslin. Lea Brothers & Co., Philadelphia. Price, $6.

A CLINICAL HAND-BOOK OF URINE ANALYSIS. By CHARLES H. BEDFORD, D.Sc., M.D. Second edition. 8vo, 172 pages, illustrated, muslin. Bell & Bradfute, Edinburgh.

TRATADO DE GINECOLOGIA. Por Dr. MIGUEL A. FARGAS. Two volumes. I, GENERALIDADES, pp. 1-299. II, ENFERMEDADES DE LA VULVA Y VAGINA, pp. 303-513. 8vo, illustrated, paper. Salvat y Ca, S. en C., Barcelona.

THE THERAPEUTICS OF MINERAL SPRINGS AND CLIMATES. By Dr. I. BURNEY YEO. 8vo, 760 pages, muslin. W. T. Keener & Co., Chicago, Ill. Price, $3.50 net.

DERBY BOROUGH ASYLUM, FIFTEENTH ANNUAL REPORT, 1903. 12mo, 47 pages.

ELECTRO-DIAGNOSIS AND ELECTRO-THERAPEUTICS. By Dr. TOBY COHN. Translated and edited from the second German edition by Dr. FRANCIS A. SCRATCHLEY. 8vo, 280 pages. Illustrated. Muslin. Funk & Wagnalls Company, New York. Price, $2 net.

THE OPHTHALMIC YEAR BOOK: A DIGEST OF THE LITERATURE OF OPHTHALMOLOGY WITH INDEX OF PUBLICATIONS FOR THE YEAR 1903. By EDWARD JACKSON, A.M., M.D. 8vo, 260 pages. Illustrated. Muslin. The Herrick Book & Stationery Company, Denver, Colo.

TRANSACTIONS OF THE AMERICAN PEDIATRIC SOCIETY, FIFTEENTH SESSION, held at Washington, D. C., May 12, 13, and 14, 1903. Edited by WALTER LESTER CARR, M.D. 8vo, 234 pages. Illustrated. Muslin.

PROCEEDINGS OF THE AMERICAN MEDICO-PSYCHOLOGICAL ASSOCIATION AT THE FIFTY-NINTH ANNUAL MEETING, Held in Washington, D. C., May 12-15, 1903. 8vo, 507 pages, illustrated.

DER EINFLUSS VON BODEN UND HAUS AUF DIE HÄUFIGKEIT DES KREBSES NACH DETAIL-UNTERSUCHUNGEN IN BAYERN. Von Dr. KARL KOLB. 8vo, 146 pages. J.F. Lehmann, München, Germany. Price, 4 M.

BERICHT ÜBER 137 GALLENSTEINLAPAROTOMIEN AUS DEM LETZTEN JAHRE UNTER GLEICHZEITIGER BERÜCKSICHTIGUNG DER NICHT OPERIERTEN FÄLLE. Von Prof. Dr. HANS KEHR. 8vo, 315 pages. J. F. Lehmann, München, Germany. Price, 5 M.

THE CHRONIC DISEASES: THEIR PECULIAR NATURE AND THEIR HOMŒOPATHIC CURE. By Dr. SAMUEL HAHNEMANN. Translated from the second enlarged edition by Prof. Louis H. Tafel. 8vo, 269 pages, muslin. Boericke & Tafel, Philadelphia. Price, $1.25.

DEPARTMENT OF THE INTERIOR, BUREAU OF GOVERNMENT LABORATORIES. Reports on—SOME PULMONARY LESIONS PRODUCED BY THE BACILLUS OF HEMORRHAGIC SEPTICÆMIA OF CARABOAS. By Dr. PAUL G. WOOLLEY 8vo, 11 pages. I. NEW OR NOTEWORTHY PHILIPPINE PLANTS. II. THE AMERICAN ELEMENT IN THE PHILIPPINE FLORA. By ELMER D. MERRILL, BOTANIST. 8vo, 36 pages. A DICTIONARY OF THE PLANT NAMES OF THE PHILIPPINE ISLANDS. By ELMER D. MERRILL. 8vo, 103 pages. THE GUTTA PERCHA AND RUBBER OF THE PHILIPPINE ISLANDS. By PENOYER L. SHERMAN, Jr., PH.D. 8vo, 43 pages, illustrated.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending July 16, 1904:

	Cases.	Deaths.
Measles	269	13
Diphtheria and croup	309	41
Scarlet fever	89	7
Smallpox	...	...
Varicella	16	...
Tuberculosis	380	134
Typhoid fever	60	10
Cerebrospinal meningitis	...	23

The Treatment of Simple Goiter by Intraglandular Injections of Iodized Oil.—Dr. Dubar reports a number of successful cases of simple goiter treated with intraglandular injections of iodized oil. He used injections of 1 c.c. once a week, but thinks that this dose could be safely increased.—*Le Progrès Médical.*

A Case of Post-basal Meningitis Due to the Pneumococcus Lanceolatus; Recovery.—J. Porter Parkinson had the following case under his care: The patient, aged two years and two months, was admitted into the hospital with a temperature of 104.8° F., pulse of 141, and respiration 70 a minute. There were definite signs of pneumonic consolidation at the apex of the right lung both before and behind. The child was small for its age, rather fretful, and had some cough. The forehead was rather unduly prominent, and the anterior fontanelle admitted the tip of the finger. There were general signs of rickets. The abdomen was swollen and the liver and spleen were slightly enlarged. There were daily, five or six loose, offensive green stools. About eleven days after entrance to the hospital the rigidity of the muscles at the back of the neck, which had existed for the previous week, was noted to be increasing, drawing the occiput well downward; gradually complete opisthotonos of the trunk muscles supervened. The legs were rigid and extended, while the arms were rigid and flexed at the elbow. The forearms were pronated, while the fingers were flexed over the adducted thumb. The patellar reflexes could just be obtained, and Kernig's sign was not well marked. There was slight bulging of the fontanelle and the fundus of the eye appeared to be normal. Two weeks after the entry to the hospital, half an ounce of clear fluid was withdrawn from the spine by lumbar puncture. It contained a trace of albumin. The Diplococcus lanceolatus with its characteristic capsule was demonstrated. The child's condition remained unchanged for about five weeks, during which time the sight appeared to be lost. The diarrhœa continued, and there was infrequent vomiting. The temperature remained slightly below normal. There was no discharge from the ear and the membranæ tympanorum were normal. After a little over two months' illness the opisthotonos gradually diminished and the sight returned. A little later a voracious appetite developed. The chief interest of the case lies in the fact that the cerebral symptoms, though clinically those of a typical case of posterior basic meningitis, appear to have been due to the Diplococcus lanceolatus and not to the Diplococcus intracellularis, as a pure culture of the former was obtained from the spinal fluid. Although most of the cases of pneumococcal meningitis complicating pneumonia affect chiefly the vertex of the brain and are said to be invariably fatal, this case appears to show that the inflammation may be chronic and situated at the posterior part of the base, and that recovery may be possible. In this case the definite cerebral symptoms did not appear till a fortnight after the commencement of the illness. They were ushered in by a further rise of temperature which continued for ten days, while they lasted six weeks.—*The British Journal of Children's Diseases.*

Middle-ear Disease and Visceral Abscess.—S. MacCuen Smith reports three cases and arrives at the following conclusions: (1) The most notable early symptom was the acute exacerbation of a chronic aural discharge, which, although usually innocuous in character, in a few cases became ichorous, and should have pointed suspiciously to a possible systemic infection. (2) The most constant and characteristic symptom was that of *severe pain* in the *right shoulder* and *neck*, which appeared synchronously with the beginning of hepatic suppuration. (3) The manifestation of pain and tenderness in the right hypochondrium unerringly indicated the liver as the seat of disease. (4) The repeated chills, unusually high temperature, and leaky skin demonstrated that the toxic process was septic in character and likely to prove fatal. (5) The marked accessions and remissions of temperature were typical of an acute suppurative hepatitis or multiple abscess of the liver. (6) While jaundice was a constant factor, it appeared so irregularly as to be of little diagnostic value, save in a confirmatory way. (7) The history of secondary infection in each of these cases is sufficiently clear to warrant the conclusion that a metastatic abscess of the liver, or other viscera, may originate from a suppurative disease of the ear.—*Annals of Otology.*

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended July 16, 1904:

SMALLPOX—UNITED STATES.

		Cases.	Deaths.
California, San Francisco	June 26–July 3	1	..
Florida, General	July 2–9	8	1
Illinois, Chicago	July 2–9	11	..
Danville	July 2–9	5	..
Kentucky, Covington	July 2–9	2	..
Massachusetts, Fitchburg	July 2–9	1	..
North Adams	July 2–9	1	..
Michigan, At 79 places	June 25–July 2	(Present)	
Missouri, St. Louis	July 2–9	3	..
Nebraska, Omaha	July 2–9	2	..
South Omaha	July 2–9	2	..
New York, Niagara Falls	July 2–9	..	1
New York	July 2–9	1	..
Ohio, Cincinnati	June 23–July 8	6	1
Zanesville	June 4–July 2	7	..
Pennsylvania, Philadelphia	July 2–9	1	..
Williamsport	July 2–9	1	..
Wisconsin, Milwaukee	June 25–July 8	9	..

SMALLPOX—FOREIGN.

Brazil, Rio de Janeiro	May 22–June 5	291	103
China, Shanghai	May 14–June 14	..	10
Cuba, Habana	June 18–25	..	1
		Source of infection probably imported to case	
Great Britain, Birmingham	June 18–25	1	..
Bristol	June 25–July 2	7	..

AGE AND YOUTH IN MEDICINE.*

BY W. W. KEEN, M.D. LL.D., F.R.C.S. (Hon.),
PHILADELPHIA.
PROFESSOR OF SURGERY, JEFFERSON MEDICAL COLLEGE.

I KNOW nothing more inspiring than a scene like the present. Before me is a company of young women and young men, recruits in the medical army, anxious to press forward to all the dangers, trials, failures, and successes of a medical life to final victory. My career will soon end while yours is just beginning. I look toward the western setting sun, you greet the eastern rising sun. Mine is the past with its splendid accomplishments, its dismal failures, its disheartening, unaccomplished tasks. Yours is the golden future, yours to renew the attack where we have failed and to win the battles that we have lost, yours to fulfil our unaccomplished tasks. Naturally, therefore, the occasion suggests a contrast between myself and yourselves, and, accordingly, I have taken as my topic "Age and Youth in Medicine."

Let me recount briefly some of the wonderful things that I have seen accomplished in the more than three-score years covered by my own life and then glance at what may be in store for you.

First, the geographical and political changes I have seen have been almost kaleidoscopic in their variety and extent.

The map of Europe has been remade. Since 1859, the year that I graduated from the University, Italy has been re-created as a united Kingdom. This new political life has been followed by a wonderful intellectual revival, so that Italian medical science and letters to-day have won an enviable place. Austria has lost her Italian possessions and has been deposed from her Teutonic hegemony. Germany has been created by the welding of two-score states into one imposing Imperial Power. Spain, one of Lord Salisbury's "dying nations," has lost her colonies and her prestige. France has been shorn of Alsace and Lorraine. The Danubian Principalities have taken the first steps toward freedom from the rule of the "unspeakable Turk," the one foul blot still existing on the map of Europe.

The map of Africa has been drawn anew since my boyhood. The "terra incognita" which well described central Africa when I first studied geography, has been explored, and Stanley, its foremost explorer, lies in a new-made grave. The sources of the Nile have been found; the Mountains of the Moon have disappeared. Egypt has been renovated by Anglo-Saxon genius. The boundless resources of tropical Africa have aroused the earth, hunger of European nations until nearly the whole of it has been parcelled out among them. A railroad will shortly connect Cairo and the Cape, and modern steamers will soon ply upon every great river of the Dark Continent.

*Address at the Commencement of the Medical Department of Cornell University, June 8, 1904.

The old map of Asia has been torn in pieces by Russia. Step by step, stealthily, yet steadily, she has encroached upon the various predatory nations of Asia and has made herself master of one after another until it seemed as though everything north of the Himalayas would fall into her capacious maw. But the new map of Asia is now in the making, and in its reconstruction, Japan, thank God, will have much to say; Japan, that wonderful country, which only emerged from feudal seclusion as I was just approaching middle life and entered upon the most remarkable career of national development ever witnessed in historic time.

And, what shall I say of America? True, its boundaries had been enlarged a century ago, but it was still only a vast virgin wilderness, over which roamed the bison, the bear, the Indian, and a few adventurous trappers. In my young manhood Indian wars were of more than annual occurrence, and practically the whole of our little army occupied frontier forts, which now are centers of a busy civilization. The "prairie schooner," slowly creeping across the plains, faintly presaged the Pacific railroads; Chicago was Fort Dearborn when I was born; St. Paul was a village and Minneapolis was a name yet uncoined when I graduated from Brown University; Texas, California, and Alaska were all added in my early years, and even you have seen Hawaii, Porto Rico, and the Philippines become possessions of the Great American Republic

In the arts and sciences that minister to the progress and comfort of man, the changes have been equally rapid and widespread. The railroad and the steamboat were just at the beginning of their marvelous development when I was born. No human face had yet been fixed by the complaisant sun on the plate of the daguerreotype, the ambrotype, or the photograph. The scythe has been replaced by mowing- and reaping-machines; type-setting and printing were done by hand instead of type-setting machines and the swift Hoe printing press. In my childhood days the rag-picker was a familiar figure on the streets, hooking over the piles of waste to find the linen rags from which paper was made, and paper, therefore, was very costly. Now, our forests are ground into paper and the modern penny newspaper has been born. I shall never forget my father's incredulity when he first read of a machine which would do the work of a woman's deft fingers, but the American sewing machine has conquered the world.

In my boyhood, electricity was scarcely known outside of the laboratory. Its marvelous multitudinous uses, to-day barely at the beginning of their development, were utterly unknown. The first commercial telegraphic message was sent in the very year of my birth—now it is one of the daily needs of millions. Its omnipresent wires have scaled mountains, burrowed under the slime of the sea, girdled the earth, and put Puck to shame as a lagging messenger. Even in late years, the telephone, the trolley, the dynamo, the electric lamp,

and wireless telegraphy have all sprung into being as by magic and soon all of our rivers will be harnessed and made subservient to the comfort of mankind.

The human hand, that most perfect instrument, has been almost driven out of the industrial market by various machines which do its work so much more cheaply and often so much better. Metallurgical processes have so cheapened the production of iron, copper, aluminum, and other metals that whereas a few years ago their use was impossible on account of their cost, they are now common household implements.

When I was in college, the so-called Fraunhofer lines were simply a curious phenomenon in the solar spectrum; yet, a few years later, they furnished us with a chemical analysis not only of the sun, but of far distant comets and nebulæ, and have determined even the velocity of light from the furthest confines of the universe. Nay, more, by means of the spectroscope elements unknown on the earth have been discovered in the sun; and now that by its means we have discovered helium and know that uranium becomes changed into radium and radium into helium, one element into another, the asserted philosopher's stone of Paracelsus and the other alchemists, by which they could transform the baser metals into gold, may possibly be found to be of more substantial stuff than dreams are made of.

Meanwhile educational endowments of millions have been made. Philanthropy cares for the children, the prisoner, the degenerate, and even the lower animals; slavery has been abolished; the International Tribunal of Arbitration will soon be housed in a palace dedicated to Peace and erected by an American, and religious liberty is enjoyed as never before.

But, with all this wonderful progress, where has medicine been? Has it kept step with the other arts and sciences or has it lagged behind? It delights me to say that it has not only kept up with the foremost rank, but has even outstripped not a few. In 1846 and 1847 ether and chloroform were discovered and the operating table was robbed of well-nigh all its terrors. Thirty years later, thanks to Lister, antisepsis added its benison to the blessing of anæsthesia, and operations have been deprived of nearly all their pain and of their former frightful mortality. These two blessings, the one making operations painless, the other making recovery almost certain, have made possible a new surgery which was not only impossible but even undreamed of when I began to study medicine. In this way have been developed the surgery of the kidney, of the liver, of the gall-bladder, of the pancreas, of the stomach, of the intestines, of the appendix, of the prostate, of the brain, of hernia, of the pelvic organs, and even of the heart. By these means the mortality of compound fractures and of ovariotomy, which used to claim two out of every three patients, is now reduced almost to a vanishing point. In fact, were my old teachers of surgery, Gross and Pancoast, to come to life, they could not even understand our modern vocabulary; and if they were to visit a modern surgical clinic, they would think us stark mad.

Moreover, we have blocked many diseases at the fountain-head by discovering their causes and the means by which they become diffused among the well. Thus we have found that the guilty culprit spreading yellow fever and malaria is the mosquito, and that the cause of malaria is a parasite whose life history is now perfectly known. The efficiency of our means for preventing outbreaks of both of these scourges of the human race will find a splendid illustration within the next few years in the sanitation of the Isthmus of Panama, which will be Chapter II in the splendid volume, whose first chapter was written in Cuba by Major Walter Reed of the United States Army. The cause of the plague and its dissemination by the rat is well known; the cause of typhoid fever and its dissemination by flies and through drinking water, and of cholera and its diffusion through drinking water, are also matters of popular knowledge. We know now the deadly cause of diphtheria, and the use of its antitoxin is making the once loud wail of parents for their lost little ones as after the death of the firstborn in Egypt to grow fainter and fainter. The prevention of smallpox has been known for a century, and lately its cause has been found by an Italian and an American. The causes of cancer, of scarlet fever, of measles, and of many other of the commoner diseases of childhood, have as yet eluded the scrutiny of the ablest men of the profession. The discovery of these is among the unfulfilled tasks to which I referred a few moments ago, which is committed to your hands.

Microscopical analysis and the chemistry of the secretions have been wholly rewritten within the past quarter of a century, while the examination of the blood as a means of diagnosis and the serum treatment of disease have made splendid beginnings. Percussion and auscultation have opened a new world to us in the diagnosis of diseases of the chest and abdomen.

Meantime numerous instruments have been added to our armamentarium, without which the modern physician and surgeon would be almost helpless. The thermometer, which has only been our handmaid for about thirty years, has substituted exactness for surmise; the hypodermatic syringe disclosed a new method of medication about the same time; the aspirator was not known till after I graduated in medicine; the ophthalmoscope has revealed an unknown world in the interior of the eye, which, with many other instruments of precision, has made ophthalmology one of the most exact of the medical sciences and a model of accurate measurement and statement for all its sister sciences. The otoscope, rhinoscope, cystoscope, œsophagoscope, and other similar instruments have revealed to us the interior of other organs of the body in a way formerly wholly unknown, while the simple hæmostatic forceps and retractors have made many modern operations physically possible.

The growth of medical laboratories within the last twenty-five years has been phenomenal. The laboratory has done much more than merely afford the opportunity for investigations which have yielded such an abundant fruit. It has cultivated laboratory methods—that is to say, methods of exactness, and the use of instruments of precision. The experimental method in medicine has done more than any other one thing to widen the boundaries of our knowledge. Besides this, it has cultivated precision in thinking, which is more important than any instrument or method. The vague theories and subtle reasoning of our forefathers are now replaced by exact methods of investigation. The difference is well set forth by Mumford when writing of Rush and the yellow fever. "Like the rest of the profession," says he, "Rush was at his wits' end, and it is interesting to note how different from modern methods were the means adopted by such men for solving the problem of treatment. In these days the natural history of a disease is worked up, its pathological anatomy investigated, and clinical and laboratory researches elaborately and carefully made in order to learn the exact nature of the phenomena under dis-

cussion and so, perchance, to find an appropriate and rational remedy. Those ancient men, on the contrary, had their preconceived notions as to the nature of the disease, and limited themselves mainly to searching the literature of the subject and to experimenting with drugs." Reasoning about the yellow fever and its effects, Rush "thought he saw that the debility indicated by the low pulse was due to the 'oppressed state of the system' [whatever that may mean] which must be relieved by purging, supplemented by bleeding."

Imagine, if you can, the forlorn condition of the doctor sixty years ago without our present means for physical diagnosis, without the thermometer, the hypodermatic syringe, the various specula and other instruments I have named, without the aid of hæmatology, of anæsthetics, of antisepsis, of the modern microscope, without our laboratories, and our experiments, our chemistry, our bacteriology and our antitoxins—without everything except his eyes, his ears, and his fingers: then you can appreciate the triumphal march of medicine during a single lifetime.

In this brief review I have given you, very hastily and imperfectly, something of what has been done in medicine during my own lifetime. What, now, has the future in store for you?

You entered the medical school in vastly different conditions from those which obtained when I began the often weary study of Gray, Gross, Watson, and Ramsbotham. I am often reminded of the time when the Chief Captain rescued St. Paul from the mob, and asked him whether he were a Roman citizen. When the Apostle declared that he was, "With a great sum obtained I this freedom," said the Chief Captain; to which his Hebrew captive proudly answered, "But I was born free." You, too, are "born free"; born to an inheritance of anæsthesia, of antisepsis, of laboratories, of improved methods of teaching, of many heretofore unknown drugs. "With a great sum" of toil, and work, and worry the men of my generation have obtained the freedom which you have inherited.

What use will you make of this freedom? First, you will improve, I trust, on our present laboratory methods and our present methods of teaching. Pathology, a feeble aid to medicine and surgery when I began my medical studies in 1860, and bacteriology, a word found in no lexicon of that date, have become veritable foundations of the medical curriculum even since I began to teach. You, in your turn, must develop other and at present equally unsuspected sources of knowledge. You will introduce new instruments of precision, new means of investigation, and will thus be able to defeat, and, still better, to prevent disease. The men who will make the most progress in the next generation will be the physiological physicians and surgeons, those who are best acquainted with chemistry and physics, and who will investigate the blood, the secretions, and the tissues in present ways more perfectly developed, and in new ways of which now we cannot even guess the method or the object. Leucocytosis, iodophilia, cytodiagnosis, cryoscopy, blood pressure—all these you will use and improve upon far more than I dare picture. Comparative pathology will enrich and broaden your views. Possibly the original suggestion of Sir Christopher Wren, of intravenous medication, which we practise to but a small degree to-day by infusions of salt solution and of adrenalin, may become one of the recognized avenues for the administration of remedies. The ultramicroscopic vision which has just been conferred upon us, by which minute particles far beyond observation with our ordinary microscopes have been made visible, has opened up a new world for investigation which may develop truths as yet unsuspected.

Ten years ago who would have believed that it would be possible to look through skin and flesh, bandages and splints as though they were not, and to see our bones and determine their state of health or disease, of fracture, or integrity; and yet to-day this is known to every layman. Radioactivity, and possibly new means for the employment of light, may open new avenues for treatment. Certain it is that your studies in immunity, in toxins, and antitoxins will give you new weapons by which to prevent or vanquish disease and confer health. We need a new and safe anæsthetic. We need new drugs, new instruments of precision, by which new properties of matter, and novel methods of physical diagnosis shall be discovered, and the beneficence of medicine illustrated by unexpected and, to-day, impossible methods of cure. In these researches, alas, I shall take no part, but I can at least goad you on to their accomplishment.

But I must not forget that I am speaking to American graduates in medicine. When I was a young man, every young graduate who could afford the time and expense went to Europe to put the finishing touches to his medical education. But the current is turning westward, and will enable us ere long to repay the great debt we owe to our European brethren by freely sharing with them our future wealth of scientific and practical knowledge and experience. We have awakened to a new life of research in the laboratories founded by liberal citizens—and no institution has more reason to be proud of a generous patron than Cornell—we have felt a new intellectual impulse in our colleges—our physicians and surgeons are alert and progressive as never before. Coincident with a great political expansion that has carried us half way around the globe, with a commercial expansion which has made the world stand amazed at what we have accomplished—if the experience of England under Elizabeth, of Italy under Victor Emmanuel, of Germany under two Kaisers is any guide—there will surely be in America an equal intellectual and scientific expansion. The future belongs to America—it belongs to you—if you but show yourselves worthy of the great inheritance to which you are heirs, and of the splendid possibilities which medicine offers you with lavish hand. You will be unworthy children of worthy sires if you do not rise to the level of these opportunities. Shall it be said that our statesmen, our merchants, and our manufacturers are abler, more enterprising, more conquering than our scientists, our surgeons, and our physicians? Nay, verily. You, new members of our own profession will assuredly prove yourselves equal to the mighty task set before you, and conquer the world by being its noblest, wisest, and most unselfish benefactors.

Permissive Milk Adulteration.—Dr. Collingridge, Medical Officer of Health for the city, draws attention in his annual report to what he calls "permissible milk adulteration" in London. Of forty-eight authorities whose opinions were collected, thirty-one had adopted in practice various minimum limits of water adulteration. The list extends from a 2.4 per cent. limit of added water to 7 per cent., sixteen authorities fixing the limit at 5 per cent. Of the other seventeen authorities, some prosecuted if below the standard, others considered each case on its merits, some were guided by the opinion of the analyst, two fixed no limits, and one did not allow added water at all.—London *Standard*.

OBSERVATIONS ON RADIUM.

By MAX EINHORN, M.D.,
NEW YORK.
PROFESSOR OF MEDICINE AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL; VISITING PHYSICIAN TO THE GERMAN HOSPITAL.

In a former paper * I have described radium receptacles for the œsophagus, stomach, and rectum. They serve the purpose of allowing radium to act upon internal organs. Similar instruments can be constructed with minor modifications for other hollow viscera.

In this paper I wish to make some contributions to the method of radium treatment, its physiology (perhaps also its diagnostic value), and to its therapeutic results in carcinoma of the œsophagus.

Method of Radium Treatment—The radium receptacles first constructed were of glass. As this substance is fragile, the question arose whether the capsule could not be made of other material. It is, of course, self-understood that that substance will be most suitable which will best transmit the radium rays. To test this I had constructed capsules of the same size and thickness of glass, hard rubber, bone, celluloid, wood, and aluminium, and subjected them to the following tests: (1) The distance was measured at which a certain quantity of radium enclosed in these capsules would produce a trace of light upon Kahlbaum's barium platinocyanide screen. (2) Photographic plates enclosed in black envelopes were exposed to radium in the different capsules for two hours; the latter resting on a key which had been placed upon the plate. The pictures were then compared with one another. The first test was applied several times. I find among my records the following:

March 19, 1904. 0.25 radium (Curie 20,000) is placed in the various capsules and the distance at which fluorescence still occurs on the screen is measured. The result was as follows:

Glass	5 cm.
Hard rubber	4¾ cm.
Celluloid	4½ cm
Aluminium, not very brilliant even nearby	3¼ cm.

March 20, 1904. The same experiment is repeated with 0.25 radium (Curie 26,000 strength) with the following result:

Glass	4½ cm.
Hard rubber	4¼ cm.
Celluloid	4¼ cm.
Aluminium	2½ cm.

March 22, 1904. The same experiment was done with 10 mg. pure radium bromide (1,000,000 strength) and the following figures found:

Glass	4½ cm.
Hard rubber	3¾ cm.
Celluloid	3¾ cm.
Aluminium	2 cm.
Ivory	2½ cm.

These experiments showed that glass, hard rubber, and celluloid passed the rays of radium better than aluminium and ivory.

The key was photographed with 0.25 radium (Curie 20,000 strength) with two hours' exposure in glass, hard rubber, celluloid, wood (lignum), and aluminium capsules. The various photographic results are here shown (Figs. 1–5). This photographic experiment also shows that glass, hard rubber, and celluloid transmit the radium rays better than aluminium and wood.

From this it is evident that glass, celluloid, or hard rubber would be most suitable for our purposes. I chose hard rubber, because it is not easily broken, is cheap, and can be conveniently worked, and I have accordingly used these hard rubber capsules almost exclusively in the treatment as well as in our other experiments.

* Max Einhorn: "Radium Receptacles for Œsophagus, Stomach, and Rectum," MEDICAL RECORD, p. 399, 1904.

In the radium treatment of internal organs it is necessary to know, how deep, *i.e.* to what extent the radium rays penetrate. It is probable that different substances vary in their penetrability. To determine this experimentally I had a metal measure case constructed 10 cm. long and about 1 cm. broad, with one narrow wall of hard rubber. One of the long sides is divided into centimeters and carries a float, destined to receive the hard rubber capsule containing the radium (Fig. 6). The substance to be examined as to its penetrability by radium rays is placed in the box, and the radium capsule is moved until only a faint light appears on the fluorescent screen, which is applied directly to the hard rubber side of the box. This distance can then be read off in centimeters. As an example, I applied the following experiment:

April 23, 1904. 0.25 radium (Curie 20,000 strength) in hard rubber capsule is placed into the float of the measuring box and the distances for the following substances determined:

Air	5¾ cm.
Water	2½ cm.
Milk	2½ cm.
Uranine solution (strongly fluorescent)	2½ cm.

June 16, 1904. The same experiments with 50 mg. pure bromide of radium (1,000,000 strength)

FIG. 1. Radiophotograph of a key through a glass capsule.

in hard rubber capsules were repeated. The distances were:

Air	16½ cm.
Water	10½ cm.

(Since the box is only 10 cm. long, the screen was removed from the box and the distance added). Among the substances examined air seems to be the best transmitter of radium rays.

Transillumination of Various Organs with Radium.—*Mouth.*—If 0.25 radium Curie 20,000 strength) is held in a hard rubber capsule between teeth and cheek and the mouth is closed a strong illumination is produced on the screen. The same capsule held between tongue and teeth produces only a faint light on the screen, *i.e.* the cheek bones may be transilluminated. Whether this method of transillumination will be of any diagnostic value in diseases of the antrum of Highmore, I am unable to say. It is worth while to determine this more accurately.

Stomach.—The attempt to transilluminate the stomach with the same amount of radium 0.25

(Curie 20,000 strength) was negative. With 0.05 grams of pure bromide of radium (1,000,000 strength), however, the organ was easily and clearly transilluminated. It is best to use an instrument resembling in its construction the radium receptacle for the œsophagus, which is provided with an opening above the capsule for the insufflation of

Fig. 2. Radiophotograph of a key through a hard-rubber capsule.

air after introduction. We might call this instrument the "Radiodiaphane" (Fig. 7).

We best proceed as follows: the patient is examined on an empty stomach either before breakfast or seven to eight hours after a meal. The patient must remove all clothing from thorax and abdomen. The radiodiaphane (containing 0.05 bromide of

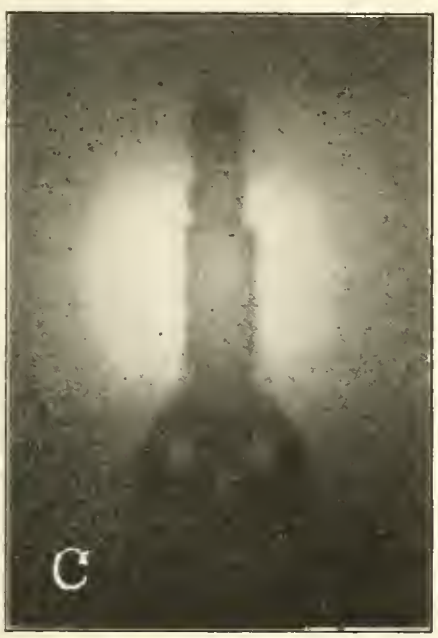

Fig. 3. Radiophotograph of a key through a celluloid capsule.

radium of 1,000,000 strength in its capsule) is slightly moistened with water and introduced into the stomach; the above mentioned Kahlbaum's fluoroscope is applied to the upper left abdominal wall and observed in an absolutely dark room. (The latter is essential, the eyes must also first accustom themselves to the darkness, which usually take one to three minutes). A figure is then observed resembling the stomach and of the color of the moon. Around this figure a feint halo may be seen to the left above the stomach up to the ensiform process, to the left axillary line and even to the left side of he back (where, however it is much fainter), *i.e.* the lungs above the stomach

Fig 4. Radiophotograph of a key through an aluminium capsule.

and the diaphragm are transilluminated. To the right the liver does not transmit the rays and the screen remains dark. If the screen is moved further down over the abdomen the illumination usually ceases below the large curvature. Besides we observe a very intense spot of illumination (about the size of a big walnut) which corresponds to the position of the radium capsule. If air is

Fig. 5. Radiophotograph of a key through a wooden capsule.

insufflated into the stomach the illumination is more marked. On deep inspiration the illumination becomes weaker (probably on account of the greater distance of the abdominal wall from the radium capsule; on deep expiration, however, the illumination becomes much brighter.

When the radiodiaphane is withdrawn, one ob

serves how the intensely illuminated area (of the size of a walnut) travels upward, to disappear in the region of the ensiform process. When the instrument again descends into the stomach, the light at once reappears.

I have practised radium transillumination in a large number of patients, and am convinced that by means of this method the position of the large curvature can be determined In patient R. D., for example, it was a finger's width above the navel; in patient N., however, who was suffering from pyloric stenosis, it reached down to the symphysis. I add a radio-photograph of the stomach of patient R. D. It was obtained by placing on the abdomen of the patient a photographic plate in a black envelope, as used for *x*-ray purposes. This was thus exposed for an hour to 0.05 bromide of radium (1,000,000) strength inside the patient's stomach. A safety pin was intentionally interposed between abdomen and plate in order to determine more easily the action of the light.

Colon.—The descending colon, or rather the sigmoid flexure, may also be transilluminated by means of radium. The radiodiaphane for the bowel is of similar construction as that for the stomach. It is only somewhat shorter and made from stiffer rubber, so that no mandrin is necessary for its introduction. Near the capsule the instrument is provided with an opening to allow the insufflation of air. Before the examination (about half an hour) the bowel must be thoroughly flushed with one to two quarts of water. The radiodiaphane is then introduced as far as is possible without kinking it, and with the patient on the back, the lower abdominal region is inspected with the above mentioned fluorescent screen. Usually there is nothing visible until air has been insufflated, when translucency occurs on the left side. If the air escapes, the screen becomes darker; if air is again introduced it becomes lighter; deep inspiration lessens, deep expiration increases the translucency. I have tried transillumination of the rectum with radium several times in patients and have always obtained the above results.

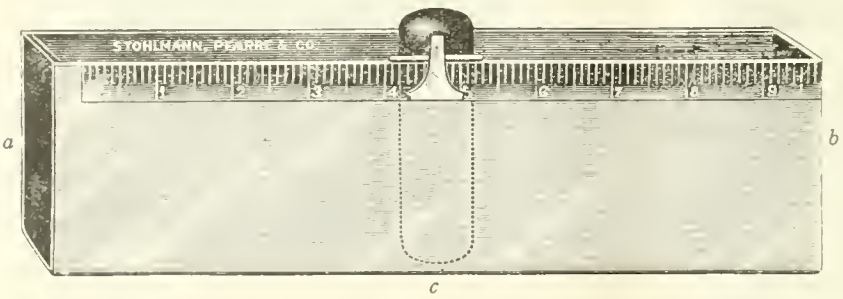

FIG. 6. Radium measure box: *a*, hard rubber wall; *b*, metal wall; *c*, capsule with float.

*Lungs.**—The lungs may be transilluminated from the œsophagus. The radiodiaphane moistened with water is introduced into the upper part of the œsophagus (the distance of the capsule from the teeth should be about 10 or 12 inches) and the naked thorax inspected with the screen. By moving the latter the lungs may be examined both anteriorly and posteriorly. Normally we obtain moonshine color wherever there is lung, only anteriorly on the left side there is a feint shadow corresponding to the heart. We would expect that marked infiltrations of the lung and exudates would cause a change in the normal translucency. This is really the case. As an illustration I will cite the following examples:

May 21, 1904. H. B., suffering from tuberculosis of the lungs, is examined with the radiodiaphane. After a few minutes we find the left half of the thorax above anteriorly and posteriorly well illuminated; the right side, however, showed a more opaque transillumination above anteriorly and posteriorly. If the screen is held toward the middle of the thorax, we see a shadow corresponding to the heart (which, corresponding with the pulse beat, shows apparently a slight enlargement) and light zones on both sides. Below and behind the lungs are also well transilluminated.

June 10, 1904. M. N., a patient of the German Hospital suffering from exudative pleurisy on the right side, is examined with the radiodiaphane by introducing it 12 inches into the œsophagus. The lungs are well transilluminated above anteriorly and posteriorly, whereas, in the lower part of the thorax to the right behind we have a shaded figure, the corresponding part on the left side being brightly illuminated. I append a photograph of the upper thorax (Fig. 9), which was obtained with an exposure of two hours to the radiodiaphane in the œsophagus (12½ inches from the teeth), in a patient suffering from œsophageal cancer (Mrs. G. L.). I had attached in this case also a safety-pin to the pocket containing the plate, which is visible in the picture.

The results obtained by transillumination are certainly interesting, primarily as a physiological fact. We see that apparently bones do not offer a stronger resistance to the passage of radium rays than ordinary muscles and skin; they are therefore transilluminated without throwing a shadow. These radium transilluminations may be of diagnostic value. The fact mentioned above, that tuberculous infiltrations and pleuritic exudates are recognizable by their shadow, seems to point to this. The radium transillumination of the stomach allows an examination of the organ laterally and to the left of the back, both regions that are inaccessible to the ordinary electric gastrodiaphane.

We may possibly be able to discover tumors in this manner. The same may be said of the transillumination of the œsophagus. At present I have yet no experience upon this subject.* Therapeutically also these transilluminations of the stomach and lungs may be of value, since they show that sufficient rays pass through these organs to be perceptible to the eye outside of the body. We might therefore expect that we would be able to subject these organs to the therapeutic influence of radium.

Radium Therapy of Œsophageal Cancer.—I have treated in all nine cases of carcinoma of the œsophagus internally with radium applications. The radium receptacle for the œsophagus was used with 0.25 Curie's radium (20,000 strength) for one-half to one hour. Otherwise nothing else was done in these cases except regulation of the diet and the occasional use of codeine.

CASE I.—November, 1903. Ferdinand S., sixty-five years old, has been suffering from dysphagia for four months. The examination with the sound reveals an impassable stricture of the œsophagus 12 inches from the incisors. Swallowing sound absent. With the œsophagoscope we see, just above the stricture, a reddened mucous mem-

*The transillumination of the stomach and lungs by means of radium was demonstrated by me on a patient at a meeting of German physicians of New York, May 27, 1904.

*Since writing this paper I have been able to diagnose once an intrathoracic and once a gastric tumor by the lack of translucency with the radiodiaphane.

brane mottled with white spots about the size of kernels of rice He was treated with radium for two or three months, on an average of about twice a week. The condition remained the same, the stricture remained at 12 inches. There was no pain. In March the patient began to cough and lost quickly; he died in April, 1904.—Result of radium treatment equals 0.

Case II.—March 8, 1904. Mrs. Esther R., about thirty-four years old, came to the German Hospital with a gastric fistula that had been made in another institution. She had some fever, a swollen liver, and an impassable stricture of the œsophagus, 14 inches from the teeth. She complained of intense pains in the chest, some cough, and irritation in the throat accompanied by nausea. The food introduced through the gastric fistula caused diarrhœa. She was treated daily for a week with radium. The pains as well as the nausea became apparently less. The objective signs at the seat of stricture have not changed. Radium treatment was discontinued because the patient left the hospital. The result of one week's treatment was negative.

Case III. March, 1904. Mrs. Esther C. W., sixty-five years old, was admitted to the German Hospital March 19, 1904. Family history: parents died of heart disease; one aunt died of tuberculosis; husband died of cancer of the rectum. Previous history. Measles and scarlet fever in early childhood. Dysmenorrhœa between ages of sixteen and twenty-four. Pain was referred to epigastrium. Has complained of sharp severe pain in the stomach for the last twenty-five or thirty years. Never had typhoid or malaria. Menopause twenty-three years ago. About sixteen months ago she suffered from abdominal pain, intermittent in character, lasting about four months; then the pain became more localized, being especially felt in the left hypochondriac and epigastric regions, pain gradually became more and more severe five months ago, it being almost constant. The pain was intensified by ingestion of food, which seemed to her to remain above and not to enter the stomach. She then started to vomit food which she had swallowed and which was practically unchanged. Meats particularly she could not retain. Patient has lost about 30 pounds in the last year and a half and is considerably weaker. Bowels somewhat constipated. Stricture found at 14½ inches from the teeth.

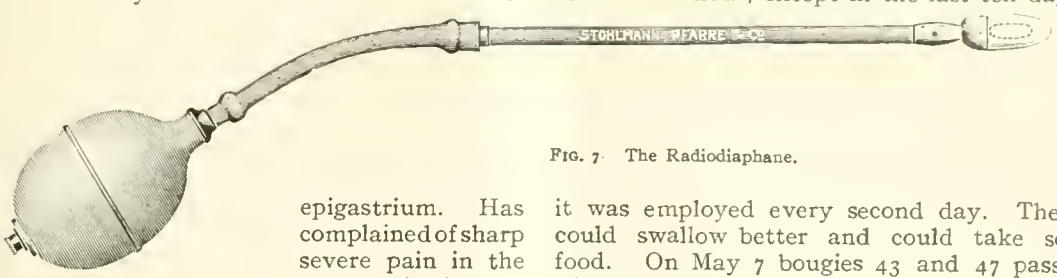

Fig. 7. The Radiodiaphane.

March 23, 1904. Gastrostomy was performed by Dr. Willy Meyer. Radium treatment (0.25 Curie, 20,000 strength) begun March 19 and continued daily from March 19 to March 22, 1904, inclusive, then discontinued on account of the operation. It was again given daily from April 1, 1904, to April 11, the day when she was discharged. The radium was left *in situ* for one-half hour each time.

April 11, 1904. Impassable stricture of the œsophagus found to be 15¾ inches from the teeth. Result of two weeks' radium treatment consists in diminishing the stricture which began originally at 14½ inches to 15¾ inches, *i.e.* 1¼ inches. The patient could swallow better.

Case IV.—April 16, 1904. Mrs. G. L., forty-eight years old, does not remember ever having been ill until nineteen years ago, when her breast became swollen and painful; swelling diminished somewhat on massage. Breast was amputated about this time. Family history negative. Four months ago the patient began to feel as though her food remained in the œsophagus for a time before entering the stomach. Shortly afterward she began to regurgitate her food, and found it impossible to eat meats or solid food. She has always been able to live on a semi-solid diet. She has never had real pain, but complains of a heaviness in her stomach. Has lost forty pounds in six months.

April 17. Bougie No. 43 passed down 12 inches from teeth, where it met with resistance; bougie No. 35 passed into stomach. Radium treatment was begun.

April 25. Bougie No. 43 passed down 12½ inches meeting there with resistance.

April 27. Radium applied for two hours, photographic plates exposed.

April 30. Bougie No. 43 meets with slight resistance at 12½ inches, which, however, is easily overcome, the bougie then passing easily into stomach.

May 3. Bougie No. 47 passed into stomach, meeting with slight resistance at about 12½ inches.

May 14. Bougie No. 43 passed into the stomach, meeting with quite some resistance. Radium treatment during this time had been applied daily for half an hour, except in the last ten days, when it was employed every second day. The patient could swallow better and could take semi-solid food. On May 7 bougies 43 and 47 passed with slight resistance. The patient felt better and could swallow some meat and crackers. Treatment was now given semi-weekly for one week, at the end of which the patient said that she could not take anything solid and that she had more pain. Bougie No. 47 and 43 encounter resistance at 12⅓ inches, No. 40 passes with slight resistance into the stomach. The radium treatment is now done every other day for a whole hour. On May 27, bougie 47 passes again into stomach; bougie 50 meets with resistance at 13½ inches from the teeth.

Objective result: the stricture enlarges from 35 to 43 F. and descends from 12⅓ to 13½ inches, *i.e.* the strictured œsophagus became entirely clear in a circumference of over 1 inch. It is now eleven weeks from the beginning of treatment and the patient has not lost in weight.

Case V.—March 28, 1904. Miss Eliza W., about fifty-five years old, is suffering from malignant stricture of the cardia, which is still passable and is 15½ inches from the incisors. Patient was treated only five days with radium, and was then operated on account of inability to take even fluid food (gastric fistula). She died a few days later.

Case VI.—April 7, 1904. Mrs. D., about sixty years old, was sent to me for diagnosis by Dr. Hutcheson. There was a malignant stricture of œsophagus, 15 inches from the teeth. On my advice Dr. H. treated the patient daily for an hour with 0.25 radium (Curie 7,000). About three weeks later the stricture was found at 15¾ inches. Objective result was descent of the stricture by ¾ inches.

(Report of Dr. Thomas Byrne.)

Case VII.—April 28, 1904. Michael G., age forty-three, complains for the last three months of difficulty in swallowing, particularly solid food. For the past two weeks he has been unable to swallow anything but liquids.

April 29. Examination by Dr. Einhorn shows that only smallest size olive tip bougie could be passed into the œsophagus as far as the lower third.

May 2. Began treatment with radium (10 milligram—strength 1,000,000) lasting one-half hour every day for the first week.

May 9. Weight 154 pounds. Passed No. 30 olive bougie with a little pressure; continued radium treatment daily for one hour.

May 16. While putting the œsophageal radium receptacle into position it slipped (*i.e.* passed the stricture) into stomach and was withdrawn without using any force. Patient says he has much less difficulty in swallowing, feels better, and looks better.

May 18. Patient eats for breakfast two boiled eggs with bread and coffee, for dinner at night eats chicken fricasee and says he had little or no difficulty in swallowing.

May 24. Passed No. 35 olive easily. Patient eats well—chicken, scraped beef; at times steak, vegetables, mashed potatoes, etc.

May 30. Radium treatment twice daily for one hour.

May 31. Weight 165¾ pounds, a gain of 11¾ pounds in one month.

June 9. The patient is examined by me in the presence of Dr. Byrne. Bougie No. 30 passes into the stomach with only slight resistance; No. 38, however, encounters resistance at 12 inches from the teeth.

Objective result: a stricture at first impassable for bougie No. 30, is now passable for that number and patient can eat better.

Case VIII.—May 25, 1904. Wilhelm A., fifty years old, while in hospital in 1904, noticed that when hungry and after eating rapidly he would have difficulty in swallowing, which was most marked in the morning. This has gradually increased until now patient can swallow only finely masticated food. About March 15, 1904, dysphagia became extreme and even fluids could be swallowed with great pain. Patient went to the German Dispensary, where he was considerably but not entirely relieved. After each meal he feels slightly nauseated and full. Has never vomited. Bowels very constipated. Pain in epigastrium after taking of food or liquid persisting until food is in stomach. Complains of salivation. Does not know whether he has lost weight, but has grown weaker.

May 25. No. 30 bougie arrested at 10¾ inches. Radium treatment, one hour daily, begun.

June 4. No. 30 passed into stomach, No. 36 arrested at 10¾ inches.

June 11. No. 36 arrested at 10¾ inches.

June 14. No. 30 passed through obstruction, No. 38 arrested at 10¾ inches.

June 18. No. 30 passed obstruction, No. 39 arrested 10¾ inches.

May 27, weight 139½ pounds. May 30, weight 141 pounds. June 6, weight 142½ pounds. June 13, weight 141 pounds. June 20, weight 140½ pounds.

Objective result: a stricture impassable for bougie No. 30 became passable for same.

Case IX.—May 3, 1904. Jacob R., forty-seven years old, began to vomit in December, 1903, about five minutes after taking of food. No pain, no tympanites, but at times acid eructations. Condition persisted until four weeks ago and patient had to go to bed. At the same time that vomiting began patient experienced difficulty in swallowing his food. The dysphagia has steadily increased until patient can at present swallow only fluids. Has lost flesh and is growing weaker. Patient once vomited fluid and clotted blood.

May 31. Obstruction of the œsophagus not admitting the smallest bougie at 14½ inches from the incisors.

June 1. Radium treatment, one hour daily, begun.

June 4. Bougie No. 30 arrested at 13¾ inches.

June 8. Small size olive point bougie passed by Dr. Caillé to 13½ inches.

June 11. No. 30 arrested at 13¼ inches, No. 21 at 13⅝ inches.

June 18. Smallest size olive No. 21 F. could be passed up to 15¼ inches.

May 29, weight 117¼ pounds. May 30, 119 pounds. June 6, 113¼ pounds. June 13, 111 pounds. June 20, 106¾ pounds.

Objective results at first a continuance of the process, the stricture ascending from 14½ to 13¼ inches. Later it seemed to recede again, and bougie No. 21 could be introduced to 15¼ inches. Constant loss of flesh.

Of the nine cases described six showed an improvement of the stricture. At the same time the patients could take food better. In three cases no improvement could be noticed; in two treatment had not been continued long enough (in Case II, Esther R, one week; in Case V, Eliza W, five days) and in a third (Case I, Ferd. S.) treatment had been too irregular to allow us to expect a good result.

Judging from the few cases that have been treated regularly and long enough, it seems to be demonstrated that a partial shrinking of the tumor causing the stricture is the rule. There were never any disagreeable occurrences incident to the treatment. A diminution of the pains could be observed in some cases, but by no means in all.

Although I could not completely cure any one of the cases, the resultant improvement is in itself of sufficient importance; the more so as we are dealing here with a condition against which we are entirely powerless (even surgically). If it is, therefore, possible to render the stricture more pervious by means of radium treatment and thus keep the patients alive for a somewhat longer time, it means a step forward.* Perhaps it will be possible to obtain even a cure in some cases by beginning treatment before the cancer has as yet progressed far. Further research on this subject is certainly desirable.

*Since this paper was written, A. Exner (*Wiener klinische Wochenschrift*, 1904, Nr. 4) has reported three cases of œsophageal cancer treated by the same method, in which there was a dilatation of the stricture as a result of the radium applications.

How a Russian Surgeon Sent the News.—A Russian correspondent of *The Times* says that the mother of one of the Jewish surgeons who were sent from Warsaw to the war recently received from her son a letter written in the usual official Russian style and bearing the stamp of the censor. The latter stated that the writer was in good health, that admirable order prevailed among the troops, who were certain of victory and amply supplied with all necessaries, and that there was so little illness that the army surgeons had hardly anything to do. It concluded with a request that his mother send some Hebrew books, of which he gave the titles. These read: "Famine and Destitution," "Consequent Fearful Epidemics," "Scarcely Any Sanitary Appliances," "Demoralization of the Army Constantly Increasing," "End of Discipline," "Wish I Were Taken Prisoner." Evidently the censor did not know Hebrew.

TIC.*

By CHARLES J. ALDRICH, M.D.,
CLEVELAND, OHIO.

LECTURER ON CLINICAL NEUROLOGY AND ANATOMY OF THE NERVOUS SYSTEM, COLLEGE OF PHYSICIANS AND SURGEONS, CLEVELAND; NEUROLOGIST TO THE CLEVELAND GENERAL HOSPITAL AND DISPENSARY; NEUROLOGIST TO THE CITY HOSPITAL.

"CHOREA! and always Chorea! as if that word chorea magically and majestically swept aside all difficulties of interpretation and comprehension." Thus passionately and truly exclaimed Charcot on being told by a patient with a generalized motor tic, that he had long been treated for chorea.

The nebulous ideas held in general regarding the relation of the various diseases characterized by irregular, spasmodic, and more or less uncontrollable muscular movement, is most regrettable.

The name chorea, meaning dance, which Sydenham unfortunately applied to a very common nervous disorder of the developmental period of life, probably of infectious origin, and which has not a dance step in its symptomatology, still clings as a nosological epitaph to a monument not erected to a philologist but to a wonderful clinician.

Chorea has been made a nosological hook upon which writers and observers have indiscriminately hung all sorts of affections which are characterized by coarse muscular trembling and irregular movement, either coördinate or incoördinate. Apparently it has been necessary only for a more enthusiastic than accurate medical observer to remark a patient with some strikingly abnormal and unwilled muscular movements appearing in any or all of the parts of the body, when he immediately proceded to burden medical literature with a new nosological monstrosity, like *chorea scriptorum*, dancing writer's cramp; paralytic chorea, paralytic dancing. Think of them! Shade of Paracelsus! Indeed we find in one of the most complete of the later-day medical dictionaries ninety-four separate affections defined as subdivisions of chorea.

Chorea is a poor term for a disease which has no dancing symptoms, and of whose pathogenesis we have no accurate knowledge. Nor has a better one been offered. Centuries of usage and its origin has sanctified and sanctioned it. It should and will be retained.

There are but two choreic diseases; Sydenham's chorea, often erroneously called chorea minor, and the hereditary involutional chorea of Huntington.

Superficial observers have likened tic convulsif to chorea both in appearance and in origin. The clinical pictures in no way resemble each other, and their origin differs more widely than hysteria and epilepsy. The only relation between the two diseases is seen in the engrafting of a tic upon a chorea; in which case tic is a sequel by suggestion. By this I mean that the substratum of psychic impressionability of youth, especially neurotic youth, is so sensitive that morbid habits easily take root. The depth and strength of this root (to carry the simile to its end) will entirely depend upon the measure and vicious fertility of this subsoil of neuropathic and psychopathic inheritance and development.

Under the titles of tic, *Maladie des tics*, tic convulsif, Giles de la Tourette's disease, mimic spasm, habit spasm, habit chorea, choreic tic, choreiform affections, one can find much written upon a peculiar disease of the nervous system, in which certain muscular movements are markedly in evidence.

In an attempt to clear the foggy atmosphere with which centuries of misunderstanding has surrounded the subject, I wish to propose an original classification that appears to me to possess not only merit, but also is more in conformity with the classification now accepted by many alienists for the better studied mental alienations. This classification is based upon the recognized periods of life which we denominate evolutional and involutional—the developmental and the senile. The classification is believed to be particularly comprehensive since it has long been the idea of the profession that tic can be broadly divided into two varieties—senile tic and early tic. The first, a result of approaching senile involution or disease; the latter that which occurs early or in the evolutional period of life and previous to the development of the involutional changes of advancing years. Therefore, I would primarily classify tic into (1) involutional tic, the so-called senile acquired tic of other writers, and (2) evolutional tic, or the so-called early tic. The first variety usually presents itself in a simple form, but not rarely may be quite complex and even associated with psychic stigmata. Evolutional tic may be divided into (*a*) degenerative evolutional tic, which is a morbid manifestation on the part of a degenerative nervous system, usually inherited, but possibly acquired; (*b*) acquired evolutional tic, and (*c*) imitative evolutional tic.

Tic literally means a knack—a trick. The word is a fitting illustration of the denominative power of the French. Tic—a knack—a trick. Motor tic—trick of movement—the knacky trick of a muscle. *Tic de pensée*—a knackish trick of thought. How perfectly expressive of the idea—how comprehensive of the varieties of the disease! It is indeed a good name and a short word. I shall use it to the exclusion of all others.

It is impossible to give a good definition of tic. The only permissible one would include a description of its most prominent symptom—abnormal musculation. It could not include anything relating to its pathology, for we know so little. Regarding its pathogenesis, we know that its development depends much upon the presence of a degenerate psychoneuropathic organism. Therefore, this is my definition:

Evolutional tic is a psychoneurosis, in which a subconscious idea tends to arise spontaneously and force recognition by externalizing itself in expressed thought (*tic de pensée*), or in the more or less automatic repetition of some stereotyped movements which are identical with volitional acts—coördinate tic.

The muscular phenomena to which the name tic has long been applied may vary in a degree from irritating twitchings of so small a muscle as the levator labii superioris alæque nasi, as once seen in a personal observation, to the most complex coördinated muscular movements associated with obsessional and compulsory ideas.

The involutional variety of tic is a convulsive or spasmodic muscular manifestation in some part of the body, usually the face, due to a pathological or involutional degeneration of the blood-vessels—arteriocapillary fibrosis. This symptom is a muscular manifestation of well-known pathological conditions of either the central or peripheral nervous system, usually expending itself upon frontoorbicularis or facial musculature. It is an affection with an organic basis, and entirely separate and apart from the form of disease to which I wish to direct your attention. I mention it for the purpose only of completing the classification. In order to place its character clearly before you, I will briefly relate two striking cases recently observed:

Mrs. P., seen in consultation with Dr. Frank Stovering at St. John's Hospital, May, 1901. Patient was sixty-two years of age, born in Ireland, and is a large woman with degenerated arteries, gray hair, and a double arcus senilis.

*Read before the Clinical and Pathological Section of the Cleveland Academy of Medicine, March 4, 1904.

Her family history is practically negative and her previous personal history good. Her husband is a healthy man and they have several grown, healthy children. Two years before my first visit she began to have a peculiar sort of "sniffing" as she called it, which consisted in a rapid, noisy nasal inspiration and expiration. Along about this time she states that she lost all her teeth and neglected to get artificial ones, and hence had considerable trouble by food getting into the buccal space, which compelled her to use very forcibly her tongue to remove it. She shortly found herself, long after eating, going through the movements, and at the same time making loud smacking noises, of which she seemed unconscious until her attention was called to them by her family. All effort on her part to control them failed. These movements were gradually added to by a peculiar pursing up of the mouth, rolling the chin about as the tongue was rapidly swept from right to left between the front teeth on the lower jaw and the lip, through both lower buccal spaces, thence to the left upper buccal space, rapidly and transversely across between the upper front teeth and upper lip to the upper right buccal space, and then again down to the right lower buccal space, to be repeated from three to ten times. At the same time the face was engaged in the necessary muscular contortions which one finds necessary in order to voluntarily produce this series of acts. All of this time loud smacking, gustatory noises were made. Always preceding the tic, which involved the tongue more markedly than anything else, the peculiar nasal respiration described, was repeated several times. An interval of rest followed when the whole surprising and disgusting series of actions, accompanied by the noises, were reinacted. If she was alone and quiet the movements were not frequent or violent, but as soon as some stranger entered, her tic entered upon a perfect debauch of sound and movement.

She was slightly melancholic and a little peculiar in some of her ideas. This tic was looked upon as an involutional tic and due to degenerative changes in the brain.

I again visited her in June, 1902, in consultation with the late Dr. John Perrier, and found her in an unconscious condition. I learned that her tic had continued since my first visit and had extended to the arms and shoulder, with rotation of the head by involvement of the neck muscles, and also a rapid, double lateral nystagmus; that her mental condition had deteriorated, and for some months preceding my visit she had complained of headache and giddiness. I felt that my former idea of the case was corroborated. The right side was paralyzed, and although she was totally unconscious some manifestations of the tic were still present. Unfortunately no post-mortem was allowed.

The second case is better shown than I can describe in the case of this gentleman who has kindly consented to come here this evening. He was first seen in consultation with Dr. J. D. Jones, September 26, 1900.

Patient is now sixty-eight years of age and gives a good personal and family history. To his knowledge there has never been any nervous affection or insanity in any member of his family.

His present difficulty began in January, 1900, when he first noticed that in making clerical entries his eyes would suddenly close. He visited an oculist, who told him that it was caused by the glasses he was wearing. He was re-refracted but secured no relief. Just previous to the appearance of his tic he had had considerable worry but no loss of sleep. He soon found himself unable to get about in the store, since his eyes would spasmodically close and he would run into objects and persons.

You will observe that he is suffering from a double facial tic, which is a very unusual form of the disease. He has a slight senile tremor of the hands and considerable evidence of arterial degeneration. Excitement or presence of strangers causes his movements to be markedly augmented both in force and frequency. They always cease during sleep. Nothing has given him any permanent relief. He thought at one time that hypnosis might relieve him, but the second sitting and all others following were without effect. His is undoubtedly an involutional tic due to central disturbances from senile degeneration of the arteries of the brain.

The first of these two cases, of many types of degenerative tic, is related to show that we may have from cerebral involution, tics which are markedly like those of the psychomotor tics observed in the evolutional period of the degenerate. Commonly the facial tic of advancing years is unilateral and more commonly, connected with the eye muscles, producing that peculiar wink which is observed in many old people, and is almost a certain precursor of grave cerebral lesion.

The following case is an illustration of this common variety:

Mrs. B., sixty-eight years of age, suddenly began to have an affection of the left eye, which consisted in its spasmodic closure, the perfect imitation of a vigorous voluntary wink. The wink was repeated several times, when a pause would ensue. If she was quiet and alone it would occur infrequently, but any excitement, especially the presence of strangers, would cause the blepharospasm to become frequent and violent. It was never present during sleep. Her arteries were degenerated and left heart hypertrophied. Four years later she died of cerebral hemorrhage. No autopsy.

You will observe in this simple case of orbicularis tic that it is the personification of the volitional act of winking, and that any excitement increased the frequency and violence of the movement.

Evolutional tic is practically always an affection of the formative period of the superior and inferior type of the degenerate. The period of growth and evolution of the victim most likely to develop tic is between the years of seven and fifteen.

It is rarely the result of direct heredity, but is rather one of the vicarious manifestations of an inherited polymorphous neuropsychopathic diathesis, commonly called degenerative. The degenerate is to his degeneracy born. But disease in early life may predispose both to its development and add to its degree. Two types are commonly recognized, the inferior and the superior.

The inferior degenerate possesses an intellect below the normal. Usually he has many of the physical stigmata of degeneracy—is club-footed, web-fingered, possesses supernumerary fingers or toes, or a cleft palate, or other less marked physical evidences of degeneracy, such as over-long index-fingers or arms, abnormal heads, misshapen ears, or other deformed features. He often belongs to the dependent class, and not infrequently the low type of criminal. Their range is from the idiot to the idiot savant.

The superior degenerate often possesses great genius; their ranks muster many decadent poets, artists, authors, and esthetes; all are abnormal, yet many possess wonderful talent to command not only notoriety but fame itself. Dryden's knowledge of the inability of these decadent people to

maintain long a normal mental equilibrium must have been full when he wrote, "Great wits are sure to madness near allied, and thin partitions do their bounds divide."

The movement of evolutional tic is a muscular spasmodic or compelled movement, identical with a movement of volitional intent. Indeed it is the muscular externalization of an obsessional idea, which is more or less subconscious.

The movements are muscular and purposive in contradistinction to the fibrillary purposeless movements of chorea. I mean by this that in the execution of the movements of tic the muscles or groups of muscles are contracted identically as if consciously willed, whereas in chorea the muscular contractions are fibrillary. The contraction of the whole muscle or group necessary for the execution of a coördinate movement does not take place, in chorea, and therefore it is irregular, incoördinate, and purposeless. I have dwelt upon this distinction to considerable extent in order that no misunderstanding of the difference can be assumed. No one with these facts in his possession and a discerning mind can observe these cases and not be shocked by such an abominable name as "choreic tic."

The movements of tic are present only in the waking state and are repeated in a stereotyped manner. They may be voluntarily repressed for a time by exertion of an energetic will, but this repression produces an inner unrest which will not be appeased until the movements are repeated. Indeed some internal and imperative demand seems to force the unhappy victim to do his stunt. I know of no disease which affords such an argument for demonomania as tic. I know of no movements so clearly obsessional as those of psychomotor tic; no thought more compelled and obsessional than that of *tic de pensée*.

It would be the utterance of but a half truth if I failed to make it plain to you that I do not hold that all tics are invariably the stigmata of degeneration. They are not. Not infrequently certain diseases in early life may induce changes in the unstable cortex and subcortical stations of the brain, interfering with the proper psychomotor apparatus of expression, and thus tend to an elaboration of the normal automatism of repeated movement

Acute specific fevers, rachitis, rheumatism, and chorea, all of which diseases present much nutritional depravity, seem to be peculiarly active in furnishing a nidus for the development of the disease tic. The permanence, severity, and type will much depend upon the vicious strength of the inherited degenerative tendencies behind the evolution of the individual's nervous and psychical growth, which we commonly call character. We must also reckon with the amount and nature of the resistance offered by a conscious or a subconscious action of the will. The simple motor tics not infrequently seen in the young, who present no unusual evidences of degeneracy, and whose ancestors have manifested no possession of neuropsychopathic development, by physical, mental, or psychical stigmata, are explainable upon these grounds only. In this class we can also consider the tics which are truly imitative, originally arising in the voluntary imitation of the muscular twitchings of others. Indeed it appears that some unstable nervous systems find comfort in the repetition of imitated movements until, at last, they become uncontrollable.

The imitative tics are rarely progressive, almost never develop the highly coördinated types marked by grotesque execution of obsessional ideas. On this basis prognosis can be confidently based.

Each one of the two varieties of evolutional tic may be divided into (1) motor tic, manifested in two forms, (*a*) localized and (*b*) generalized tic; (2) psychomotor tic, which may be divided into (*a*) a form of tic which is a motor response to a compulsory idea or obsession, and (*b*) "a tic caused by coördinate movements associated with intellectual and emotional externalization, orderly or disorderly." Pursuing this subject of classification to its logical end, the motor tics may be further subdivided according to their topographical situations. Such classification is convenient, since it facilitates description of cases and conditions.

Before proceeding to the topographical classification it is well to remember that any muscle, group of muscles, or the whole musculature of the body may become the seat of the muscular twitchings of tic. Granting the truth of this statement, it is obvious that the classification of the various motor tics would be almost interminable. The disease, however, more frequently attacks certain muscular groups, which allows us recognition of at least eight well-known forms. The arrangement is intended also to present their order of frequency: First, fronto-orbicular tic. Second, Nasal and naso-orbicular tic. Third, Facial tic. Of these three forms they are usually unilateral, but occasionally they are bilateral. Fourth, Nuchal tic, more commonly known as spasmodic torticollis. Fifth, Respiratory tic, or tic of the diaphragm. Sixth, Bowing tic, or tic salaam. Seventh, Stringhalt tic. Eighth, Lingual tic.

The following case is an illustration of a simple localized motor tic with no discoverable psychic stigmata.

Case IV.—Helen S., aged seventeen years, Hungarian Jewess, was referred to me by Dr. M. Rosenwasser, February 24, 1903.

The patient is a strong looking girl and has been in this country six years, and has never had any severe illness. She is the eldest of six healthy children. Her mother is living at forty-three and healthy. The father is also forty-three, a Jewish Rabbi, and appears to be a healthy man. No history of nervous or psychic affections in the family. Notwithstanding this seemingly favorable history, it is observed that the father has stigmata of degeneration, and it is believed that he is an excitable, irrascible man. The patient herself presents deformity of the palate, a peculiar shaped head, and a marked Darwinian tubercle of each ear. She says that she is extremely excitable and that she is very passionate, becoming angry with little or no cause. She is clearly a type of superior degenerate.

About nine months before coming to my office she began to have a peculiar movement of the right ear, which also seemed to involve a part of the right forehead. This movement consisted of elevating the ear about a quarter of an inch straight upward, and immediately afterward a movement began which drew it back a like distance, when it would slowly fall to its usual elevation. This movement seemed to be principally due to the contraction of the auricularis superior and posterior, and possibly some of the fibers of the temporal muscle were involved. There was a marked enlargement of the turbinate bone of the right nose, and in addition the Eustachian tube on that side is closed. The patient was referred to Dr. Lenker for special treatment.

Case V.—The following case is related as an instance of motor tic more disseminated and widespread than I have ever witnessed in a patient who presents no marked psychic aberrations. While the patient is not absolutely free from psychic symp-

toms, yet it is possible to explain all that she has because of a sensitive nervous system.

Miss B., aged twenty years, was normally born of parents usually regarded as healthy, but examination into the history reveals that the mother is not only a neuropath, but has decided psychopathic tendencies. The father is rather an irritable man, without, however, possessing the amount of mental balance to make him the success to which his talents actually entitle him. I would therefore class both father and mother as superior degenerates. The daughter, and the only child, is remarkably free from degenerative stigmata apart from her tic. She was bright and apt in school, and never suffered from any severe ill health until the present illness.

Three years ago, and shortly after she had returned from an extended visit to eastern relatives, it was noticed that she had a habit of making peculiar jerking movements with the hands and shoulders, very much like the gesture understood by the term shrug. While eating at the table she also sat with the elbows held far from her sides. She seemed to find these movements more or less necessary while eating, for which she was reproved. The position of the elbows was noticed preceding her visit. Her mother observed when she returned that while eating she held the elbows tightly against the trunk and in such an awkward manner that she was again smartly reproved. This peculiar position was soon supplemented by her sitting on the extreme edge of the chair and bending forward toward the table. She was reproved smartly and repeatedly, especially by the father, for the peculiar movements and ridiculous postures. She had always been unduly sensitive, and, like her mother, blushed at the least thing. The reproofs seemed merely to aggravate her condition until shortly she found herself unable to sit at the table with her father because of the violence of the motions of hands, arms, and shoulders. Shortly they increased until she was unable to eat in the presence of her mother, and finally became so pronounced as absolutely to prevent her sitting at the table, and for over one year and a half all of her food has been taken while standing in a room apart from anyone. She soon became so sensitive about her terrible condition that she could not be coaxed to go out of the house, in which she has remained for over one year. These tic-like contractions extended to the neck, drawing the head backward and the body sharply to the right side, indeed so marked was this lateral deviation that she appeared to have a curvature of the spine. These conditions were in full force when I saw her.

To physical examination she seemed a healthy girl. There were no changes in the reflexes, nothing whatever to indicate any profound disturbance of the nervous system otherwise than manifested by her tic. The heart, lungs, and abdomen were normal, and there was apparently nothing to indicate that she was suffering from any obsessional ideas, or any of the marked psychic manifestations of tic. I believed then, as I do now, that her peculiarities in eating were the result of fear of reproof. At all times her tic is greatly increased by the presence of strangers. It ceases during sleep, but at times is so extremely severe that it is almost impossible for her to maintain a standing posture, especially if embarrassed. She is growing slowly better, but of late has entertained exaggerated ideas as to the way her family should live, and has made some suggestions for improvement, which, knowing her family's circumstances as she does, she ought to realize as impossible.

It is to be noted that each of these cases are incoördinate in movement. The difference between an incoördinate and a coördinated tic can be illustrated in the following case:

Case VI.—A male, white, aged twenty years, first developed a movement of the head and neck as if his collar was ill-fitting or uncomfortable. Now this was a simple tic with little coördination of movement, but when a few months later he accompanied the neck movement with an extension of both arms and a quick grasp of his fingers as if to pull down his cuffs, we had a perfect example of a complex coördinated tic and an excellent illustration of the merging of one variety into another.

Case VII.—The following case is one of the most remarkable of its kind that I have ever had the opportunity of studying. It illustrates an acquired tic of profound psychopathic type, with a great degree of coordinate movement, and also affords an excellent example of the tendency of the tic disease to repeat itself under proper stimulus.

Mrs. A. G. was referred to me by Dr. Gregg of Wellington, Ohio, July 18, 1902. She was born in the United States thirty-four years ago, is married, but is living apart from her husband. She has two healthy children, one six and the other two years of age. She has never had any miscarriages and has never lost any children. As a child she was rather delicate. She was attacked with whooping-cough at six, which was followed by a difficulty quite similar to that from which she now suffers. The affection persisted until after puberty, when it gradually disappeared. The father and mother are both living and healthy. She had one brother, who died at sixteen of some kidney difficulty. The father, who accompanied her to my office, appears to be a healthy man and free from marks of degeneracy. I could not learn anything to cause me to believe that the mother was neurotic or a psychopath. Her grandparents lived to a ripe old age. One maternal uncle suffered from epilepsy, which is the only history of nervous disease obtainable in her family history. Four or five months preceding the birth of her last child she began to present a tic of the diaphragm. At this time she was having trouble with her husband and which caused her to worry very much. She now states that she does not worry, but that her tic has grown from bad to worse until she is now in a deplorable condition.

The patient is a tall, strong woman, light brown hair and blue eyes. Her sight is good and all other special senses appear normal. There are no signs of any disease diathesis, nor of presenile degeneration. Pulse is 120 to the minute, but she confesses to the fact that she is very much more agitated than usual. There are no stigmata of hysteria, and outside of a small head her stigmata of degeneration are few and not marked. Her knee-jerks are normal and equal, but the wrist-jerks are plus, and she has a slight jaw-jerk. The most striking thing is her respiratory tic.

She breathes rather superficially for a number of respirations, then she takes a very deep inspiration accompanied by a sound, during which a-h-h-h-h-h is prolonged, the h being carried over in the expiration and gradually exchanged into an a, which is carried to the end of the expiration—thus, a-h-h-h-a-a. The inspiration is labored and rather slow, and after taking several such she places her hands on the sides and says in a very satisfied tone, "There, I feel rested now." In watching these movements, when the chest is bared, it is noticed that the inspiration is very deep and prolonged almost to violence. The shoulders are lifted upward and the subclavicular spaces are deepened to a remarkable degree. Between these marked respiratory spasms

she produces a peculiar sound, a belching sound, which is evidently due to swallowing air and then throwing it up through the œsophagus with a great deal of force. Believing that she was aërophagic—an air swallower—I placed my finger below the pomum adami, when the slightest pressure caused her to make an effort to vomit, and she stated that she could not breath, although she did not appear to be cyanosed.

She is markedly dermographic. One could draw a map of Africa on her skin without trouble. In addition to the diaphragmatic tic there appears to be a tic like spasm of the abdominal muscles. During the whole of the examination she continued working with the right hand, pinning and unpinning a pin on her dress over the left knee. Her fingers are sore and calloused by pricking them while engaged in this act, and the dress is in shreds. On the left forefinger is a ring made of many strands of common cotton thread. This ring is continuously being rolled from the forefinger to the thumb and back again with almost inconceivable dexterity and rapidity. On her little finger is a similar ring, which is operated in a like manner but less frequently. On account of her respiratory spasm she has great difficulty in eating, but less trouble in drinking. She is able to eat much better when alone. She is distinctly melancholic, and although she very successfully conceals every subjective evidence of her psychosis, observation convinces me that she also suffers from counting mania.

She cannot explain why she does these peculiar things, but states that she has no rest unless she repeats them. If she is asked a question she invariably takes one or two of the very deep inspirations immediately followed by the swallowing of air and the belching sound, before she answers. During the concentration of her muscular energies in producing the diaphragm tic, the coördinate movement in reference to the pins and strings are inhibited, but are again immediately resumed.

Case VIII.—Marcus S., aged thirteen years, born in United States, of Hebrew parentage. He was always a delicate child, nervous and fretful. I have observed his growth from infancy, and it has been characterized by many nervous symptoms. Mother is a large healthy woman of tuberculous parentage. The father is a superior degenerate, extremely excitable, is rheumatic, and has a neuropsychopathic ancestry.

Marcus suffered a slight chorea at eight, after which he had a tic of the face, which persisted for nearly a year and consisted of a peculiar sniffling and gustatory noise, evidently produced by the tongue. Two years ago he again came under my observation because of nervous twitchings and a peculiar movement which consisted of drawing the knee upward until he could put his hand in at the top of his stocking, in which he would insert his forefinger and run it around between the leg and tocking, repeating this peculiar obsessional movement many times a day in spite of rewards, threats, and punishment. A prolonged trip in the country, sumbul, arsenic, and iron relieved him. In March, 1903, he was again brought to me because of a peculiar complex, coördinated tic, and although he stoutly maintained that he could control this tic, nevertheless he repeated the movements at least four times in my presence during his first visit to my office. The movement consists in placing the right forefinger on the upper lid of the right eye so as to evert the lid, and then applying the next finger to the lower lid until the lower lid is pulled down and the eye pulled open. The ball is turned upward and inward at the same time and with a sudden twitch the forefinger is brought into the external canthus of the eye, much as one would in attempting to remove a foreign object, the movement is complete and the imperious demand of a subconscious idea satisfied. You will observe how these acts appear volitional and like habit development. They are not. They are compelled.

The boy is a superior degenerate and bright in school, but is unruly at home and promises to be a great trial to his parents. His saving grace up to the present time is an inordinate love for all forms of out-door sports; it has already overcome much and is his only hope. He also has nasal obstruction and hay-fever, for which he was sent to Dr. Leuker.

Case IX.—In Dr. Tooth's clinic in London, I once observed a child presenting a very complex coördinate tic. The movements of which were executed as follows:

The child would suddenly balance itself on the left foot, and when it appeared satisfied with its equipoise the right toe was accurately applied to the Achilles tendon of the left heel, and slowly moved upward and downward. At the same time the chin was thrust forward and the back of the right hand vigorously rubbed the whole length of the forehead and nose. This movement had been repeated so many times during each day that the heel of the shoe was worn through and there was not only a callus upon the forehead and nose, but also upon the back of the hand.

The following case of tic with coprolalia aptly illustrates an interesting phase of this little-studied disease:

Case X.—Isaac L., aged thirteen years, was born in the United States of Jewish parentage. He is the third child of a family of seven; all of them are more or less neurotic. The mother states that the father is healthy; she herself is a degenerate and suffers from both hysteria and neurasthenia. A maternal uncle became insane and committed suicide.

Isaac is a well-developed boy, was always backward in school, but has never suffered any severe illness. At the age of eleven he had a winking tic, which was looked upon as a habit spasm. It was noticed, however, that at that time he had peculiar movements of the head in which the chin was retracted and lowered while the occiput was drawn far backward. His mother said that he had always been a willful child and given to profane and obscene language. He came under my care at the out-patient's department of the Cleveland General Hospital six years ago. Examination determines that he is a degenerate of inferior type. His ears are misshapen, features irregularly formed, arms over-long, and he has some lateral deviation of the spine which brings the left shoulder lower than the right. Muscular relaxation allows the scapula to protrude, which accentuates a kyphosis that seems to extend from the fifth cervical to the sixth lumbar. Across the shoulders, and also across the loins is quite a marked growth of light brown hair. During the whole examination he kept up an inspiratory tic accompanied by a peculiar movement of the head similar to that before described. Nasal respiration is free and the tonsils not enlarged. The reflexes are apparently diminished in strength. Shortly after he came under my care he seemed to grow worse and the movement of the head was altered in character, the chin being turned over the right shoulder. He was taken into the Cleveland General Hospital, where it was discovered that he had a marked coprolalia, and to it was due much

of the profanity and obscenity of which his mother complained. The head would be turned over the right shoulder, two or three sniffling sounds accompanied by gutteral noises made and immediately afterward, without any reason or cause, he would fairly explode cuss words or some obscene filthy expression, usually consisting of but one or two words. He was prompt to tell you that he was unable to control this, and, in fact, unless some one remarked it to him, he seemed unaware that he had said anything out of the ordinary.

The following case was referred to me by Dr. Alfred Maschke, and serves to illustrate a type that cannot be separated by clearly defined lines from other degenerative diseases of the evolutional period of life, such as the abortive type of dementia præcox, evolutional neurasthenia with obsessions, and hysteria with its disordered emotions and multitudinous compulsions. The marked catatonic posturing; the echolalia or word echoing; the echokinesis or mimicking movements; imperative conceptions, such as counting the spoons of sugar (arithmomania); the *delerie du toucher*, or mania for touching things; the phobias, such as fear of water, and fear of changing clothing, render the case both interesting and confusing.

Case XI.—Etta L., Jewess, aged eighteen years, the eldest of three children. She had a natural birth and never experienced any violent illness.

Her mother suffered from lactational melancholia and once attempted to throw her children out of a window, and is a markedly nervous, excitable woman. The father is a quiet man, but possesses an unusually large number of physical degenerate stigmata. The mother had one brother who was a victim of neurasthenia, which was marked by obsessional ideas and delusions.

Etta was said to be bright in school and was well until two years ago, when she began to be tortured by a feeling as if she had a tight cap on her head, and a sensation that the child behind her in school was pulling her braid of hair. Shortly after this she began to have hysterical and neurasthenic symptoms, and was troubled with globus hystericus. She next developed a mania for feeling the pulse, next that of looking in the mirror and making facial contortions and stereotyped gestures. She neglected her personal appearance, would neither wash nor drink because the sight and touch of water "upset" her; she manifested fear of crowds, fear of food; soon after this she developed a marked tic of the diaphragm, and shortly began to echo-like repeat the last part of sentences addressed to her—echolalia. She has an arithmomania, counting each spoonful taken while eating; counted the spoonsful of sugar put into her coffee, and when she sat down to the table would rapidly touch each plate, dish, fork, knife and spoon within her reach. She developed a great many stereotyped actions, which were repeated over and over until she was stopped by repeated reprimand. Many of her posturings were suggestively catatonic. When I first saw her, an aunt summoned me cautiously to a door where, by peering through some draperies, I could see the girl sitting alone, with her hands in her lap. The aunt passed through the room and spoke to her and then went out, leaving the girl supposedly alone. The moment the aunt left the room the girl stretched her arms high in the air; then bringing her fists down she beat her breasts with great rapidity; and then stretching her arms out in front of her she rapidly rotated them, allowing the fingers to hang loosely; all the while the head was rapidly rotated from side to side. This she continued for a period of perhaps a minute, during which time she emitted a sound very much like that of a grieved puppy. She was undersized, elflike in appearance, possessing many physical, mental, and psychic stigmata of degeneracy. She had all sorts of obsessions and compulsions. She was hysterical; was ill-tempered, and her intellect was not of high order. She was a marked type of inferior degenerate. No organic disease could be found, and outside of the polymorphic manifestations of hysteria, dementia præcox, catatonia, and tic, no actual disease of the nervous structures existed. Perhaps you think she had enough; I am sure of it.

Treatment was not attempted in her case, because the coöperation of the family could not be secured.

I hope you have not been wearied by the unavoidable prolixity of my relation of the details of these interesting cases. In all of the cases of psychomotor tic you may perceive the presence of the dominant idea. Such compulsions have been noted in those not subject to any marked departure from the normal. The oft-quoted example of Samuel Johnson's compulsion, which was manifested by his touching every post he passed, is but an illustration of a rather common dominant idea, that to perform some formulated or stereotyped act or to repeat either in thought or words some fixed formula is necessary in order to satisfy an inner whim of the subconscious brain.

I recall numerous instances of arithmomania. One, a prominent jurist of this city consulted me in reference to this dominant idea which had tyrannized over him so remorselessly as to cause alarm. He assures me that he counts the windows in the cars; the windows in houses on the street; the steps up to the Court House and City Hall; the number of men at the trial table; the witnesses; the jury in the box, and the shining heads of the brass nails of the court-room chairs.

I also recall a boy of nine years, a bright degenerate son of an alcoholic father, who invariably smelled of each article of food taken into his hand. Threats, rewards, and punishment by the proud mother had little effect. When last I saw him, a well-grown lad of fifteen, he told me that he could control the dominating idea only by putting his whole mental forces on the alert. If he relaxed his vigilance he was certain to be humiliated by finding himself smelling of the first article of food which his fingers touched. He must especially exert the will to keep himself from smelling of a hot biscuit or roll as he breaks it apart.

612 Prospect Street.

SOME PHASES OF CHRONIC LARYNGITIS.*

By Z. L. LEONARD M.D.
NEW YORK.

In writing of this particular form of disease of the larynx, Lennox Browne said it was by far the most frequent form with which the specialist has to deal. The word physician might appropriately be substituted for specialist because some variety of chronic inflammation of the larynx falls to the care of every practitioner. It is not until symptoms become grave or annoying, usually, that the aid of a specialist is sought.

From the very fact of its prevalence less interest naturally would be aroused in the mind of the observer than would occur in the event of there being an element of rarity or obscurity attached to it. By just so much, however, the subject ought to be one of concern and should demand the respect which is due to any disease process the near or more remote conditions of which might be fraught with greater danger than it is customary to ascribe to

*Read before the Medical Society of the State of New York.

ordinary chronic catarrhal inflammation of the mucous membrane in another spot.

From the extreme of a congestion and hypertrophy excessive and aggravated, as seen in that type represented in the chronic alcoholic with hoarseness, dysphonia, and coarse, raucous cough, to that in which there is barely a trace of congestion along the border of the vocal cords and the interarytenoidal space, the intermediary might be crowded with a multiplicity of forms much too numerous to be described within the limits of this paper. Some certain symptoms are, however, likely to be met with in almost every variety which would go far to make the clinical picture homogeneous and would limit the area of treatment essentially to narrow bounds.

It is assumed that at this day every physician is competent to use the laryngeal mirror and to differentiate the commoner diversities of involvement of the larynx, and that the hour has passed when the attempt to relieve or cure a purely local affair by expectorant mixtures taken into the stomach is the ordinary routine practice.

It seems worthy of reiteration that this local manifestation, apparently of trivial importance when compared to other disease, is, on the contrary, a matter of more serious consideration not only with the view to prolong life but also to assist its victim, if otherwise sound, to a state provocative of greater comfort and usefulness.

Bearing these facts in mind, it might conduce to the value of a discussion if the salient points in selected cases were enumerated, leaving out speculative theories and setting forth what was estimated to be marked characteristics of these few types. It would also be a means of exchanging ideas in reference to the most suitable plan of alleviation.

With no further preliminary, the first example to be cited, with some of its conspicuous details, was that of a young woman of twenty years whose complaint was that she had been hoarse and coughing for twelve weeks. The family history was perfect so far as tuberculosis was a known factor in causing the death of any of its members. The patient's health had been good, with the exception of this attack, since early childhood, when she had the various exanthemata. During the twelve weeks of her illness she had lost flesh and courage, laboring under the belief that she had consumption. A teasing cough with little expectoration gave her no relief either day or night. Upon inspection the pharynx was pale; the larynx also partook of the same anæmic appearance. The lower, or cartilaginous portion of the vocal cords was congested and thickened. The interarytenoidal space was swollen and abraded, exciting suspicion at once that there might be tuberculous infection, but the sputum was devoid of the presence of bacilli. It was regarded as a suspicious case and one to be carefully watched. Except for a rather mild bronchitis, the lungs were healthy. For three weeks this patient received local treatment to the larynx with a subsidence of the cough when it was deemed advisable that a change of scene would hasten recovery. For three months she remained away from the city in a quiet rural neighborhood at an altitude of twelve hundred feet above the sea level, following explicit directions as to treatment, which was that of inhalants. Upon her return to the city all of the vexing symptoms had disappeared and the patient shortly passed from notice. Six months later she had no recurrence of the throat trouble and had been constantly occupied at her former vocation.

Another type of the various forms which have come under observation was as follows: A merchant of forty-five years, robust and of healthy parentage, who was active and athletic in his mode of life, He had, however, been given to indulging in dietary excess, using likewise liquors and tobacco freely. This man had an irritating cough and a husky voice, the result of recurrent attacks of laryngitis extending over a period of years. At the time he was first seen he had just returned from a trip abroad, where he had taken a course of waters at one of the well-known Spas, receiving the assurance that there would be no return of his throat trouble for at least five years. The pharynx and all parts of the larynx were of a purplish red appearance and extremely sensitive, so much so, that the merest touch with a probe was sufficient to bring on a spasm of the glottis. The vocal cords were deeply congested and thickened, their excursion being considerably restricted, due to faulty action of the abductor muscles. This patient having suffered so much and for so long was ready to adopt a plan of treatment enforced by a strict regimen. He became amost abstemious in his habits, and after a few lapses was convinced that if he wished to escape distress he must follow the rules which were chosen for his guidance. Assuming that it was a gouty diathesis that must be kept in mind, and the condition of the larynx a local manifestation, general treatment was pursued with the blandest measures to the larynx in the form of steaming. The patient was kept under control quite willingly with a gratifying result. The deep congestion gradually disappeared and the voice tone resumed very nearly its normal sound.

A third variety was that in a man of spare build, fifty-seven years of age, of exemplary habits and healthy ancestry. His adult life had been spent in active professional duties, during which time he had scarcely absented himself a day from his office. His anæmic appearance suggested that this might be one of tuberculosis. Repeated examinations had failed, however, to discover any bacilli and medication, for specific infection had no appreciable effect. The lungs were in no way involved, the disease being entirely supraglottic. For many years there had been chronic nasopharyngitis with much gastric disturbance. Upon inspection the pharynx and palate were of a fiery red color, angry looking, as was also the whole of the larynx, all portions of which were in a state of hypertrophy. The vocal cords could scarcely be recognized on account of the tumefaction of the ventricular bands. The interarytenoidal space was filled by a projecting mass, while the epiglottis looked like true œdema. It was firm, hard, and of even contour. There was dysphonia with moderate cough, not disturbing the patient at night after once falling asleep, and free expectoration. The rhinitis and pharyngitis responded to treatment within a few weeks, so that he was sent to the country for a more complete rest. He reported once each week for treatment. After trying many different remedies the spraying of pure alcohol into the larynx gave this patient the most comfort, so that he expressed a preference for this medication to anything else. He was not permitted to use his voice, but made known his wants by means of writing or signs. Eight weeks' absence in the hills brought him back to the city in an improved state, and he was able to use his voice somewhat. He returned to business with such renewed zest that he suffered a relapse with considerably more swelling of the epiglottis than at first. The amount of pain now present gave evidence to the fact that the deeper structure of this cartilage was affected. Cessation from business and from the

attempt to use the voice ameliorated the symptoms, but he was again directed to remove from the city, this time to a warmer climate to escape the rigors of a Northern winter. Then there was impressed upon the mind of this patient the necessity of a close adherence to such conduct as would prevent any repetition of former painful experience.

The last to be mentioned is the case of a woman, twenty-eight years of age, who was under observation a year, being treated for nasopharyngitis and laryngeal inflammation of the catarrhal type. One parent had died of what was presumably tuberculosis of the lungs. This patient was very susceptible to atmospheric changes, taking cold easily, always confined to the upper air-passages however. Rarely was there much bronchial affection. The usual remedies were applied to the membranes of the nose and throat with improvement. There had been a recurring laryngitis for several years, mostly relieved by expectorant cough mixtures, but which had never been fully recovered from. The larynx on first sight was rather paler than ordinarily. The posterior portion of both cords for a third of the distance was reddened along the edges. The arytenoids were slightly enlarged with a superficial ulceration at the interarytenoidal space. This ulceration entirely healed under treatment, while the patient's general condition steadily improved to such an extent that she was competent to undertake and to accomplish more than she had done for some years previously.

Indiscretion on her part by exposing herself to prolonged cold and wetting brought on a severe attack of laryngitis with bronchitis. This attack resisted every effort for its betterment. The cough was almost constant, to be relieved only by pretty large doses of morphine. The severity of this last onset was confined to the posterior commissure, one of the cough spots of Stoerk. This place was constantly bathed in mucopus, which was with difficulty cleaned away. The case progressed rapidly despite all treatment. There was consolidation of the left apex, with all the symptoms of tuberculosis, which was verified on finding the tubercle bacilli in the sputum. Examinations previous to this last invasion had failed to discover them. With a long catarrhal history, and the fact that a parent had died of phthisis, would lead one to judge that, given the proper opportunity, such a patient as this was would eventually succumb to the tuberculous infection.

Although with a paucity of detail, these few cases which have been quoted may well be adequate to emphasize the necessity of well-directed treatment and recognition in every case which comes under notice. These patients ought not to be put off cursorily, for, without doubt, a large proportion of them eventually yield to tuberculosis where proper attention at the beginning might avert such a calamity.

It is precisely in these cases that one ought to insist upon stringent rules with the object of securing a return to a normal state of health. Even in the simple catarrhal inflammations there should be an insistence upon rest to the injured part, and frequently a sojourn, for a time at least, to another section of the country from that in which the patient may be living. There may be occasions when a change of occupation would be deemed imperative, especially when it is considered how potential for future evil these fancied slighter ailments are.

There may be as much thoughtlessness and failure to look ahead in the troubles incident to the nose and throat, as, for instance, often happens in the care of the ears. When it becomes established that there is serious complication, it is too late to do more than to attempt to obstruct further progressive movement. Unfortunately, too often this becomes a hopeless task beyond human capability to cope with.

It is as well the duty of the physician to prevent disease as it is to cure, and to instruct those who have his confidence in the wisdom of safeguarding their health religiously. The French have a proverb that at forty every man is either a doctor or a fool. It is a laudable ambition to endeavor to lessen the number of fools in the world.

My object shall have been attained if in these limited words the impression shall be given that chronic catarrhal inflammation of the larynx, by no means incurable, deserves the most careful and painstaking management.

THE RECENT PROGRESS IN GENITO-URINARY SURGERY.*

By MARTIN W. WARE, M.D.,
NEW YORK.

SURGEON TO THE GOOD SAMARITAN DISPENSARY; ADJUNCT SURGEON MT. SINAI HOSPITAL; INSTRUCTOR SURGERY, POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL NEW YORK CITY.

My remarks will be limited to but some of the advances in the surgical field of genitourinary diseases, for it is by no means possible at any one moment, with the great wealth of literature at our disposal, to grasp all.

Beginning with the earliest period of life, we can report progress and a distinct gain in the operation for the relief and cure of the distressing condition of ectopia vesicæ. Maydl's operation offers this, by transplanting the ureters, embracing an elliptical portion of the bladder, into the sigmoid flexure, without risk of an ascending infection. This operation, though, is adapted at present to those who have survived the tender years.

A more commonly encountered affliction, readily relieved by the knife, is that of hypospadias. The plastic, jointly described by von Hacker and Beck, offers the patient the distinct gain of urinating more cleanly, for procreation, as is well known, is not influenced by the hypospadias. It is the consensus of opinion that this tunnelling operation is most effective and the cures are lasting.

For undescended testicle in the earliest years, as heretofore, the gentlest of massage and traction efforts are in place. Operation under ordinary circumstances should be postponed until the age of puberty. At this time, if there are indications such as pain, neuralgia or swelling, an artificial gubernaculum should be formed out of the tunica vaginalis, to aid in anchoring the testicle.

In this connection it is opportune to allude to a condition of increasing occurrence, viz., torsion of the spermatic cord. It simulates strangulated hernia, and demands castration. Exceptionally, the twist may be unraveled.

Castration has seen no modification of late, save that it is the better practice for most of the conditions to castrate very high, following up the structures to the internal ring. It happens occasionally in congenital hernia, while dissecting the sac, that the vas deferens is divided. If it be sutured end to end, there need be no doubt as to the thorough restoration of the lumen of the vas, and consequently no danger of the testicle undergoing atrophy.

The vas deferens has also been successfully implanted into the head of the epididymis, where the latter was resected for localized tuberculosis, with all the evidence of regeneration of the tubules.

*Read before the Eastern Medical Society of New York, March 11, 1904.

This procedure is warranted, if we can feel certain that the vas deferens is itself not invaded by disease ascending from the epididymis. In such instances, following castration as high as possible, the vas deferens should be drawn upon, when it will be found to tear at the site of disease. Opposed to this crude procedure, it has been suggested by von Büngner, to inject into the vas deferens solutions of iodoform, so as to treat the disease existing beyond. Such injections are rendered easy because of the thickening of the vas, and may also be made into the vas deferens at the stump of castration.

With this consideration of the surgery of the vas deferens we have covered all that appertains to tuberculosis of the epididymis, save to refer to the difficulty of diagnosticating and differentiating this disease in its incipiency. For this purpose the use of tuberculin at times is efficient.

Epididymitis of gonorrhœal origin has also been relieved by surgical means. In the acute stage, where the tension is great, some of the fluid in the tunica vaginalis may be abstracted by aseptic puncture.

The older methods of operating hydrocele have been replaced by the simple and efficient method of eversion of the sac. A small percentage of failures is reported following its use. Its advantages are the rapidity and readiness with which it can be applied, it being possible to do the operation under cocaine and to allow the patient to be about within a couple of days thereafter.

This principle of eversion of the sac has also been applied to congenital hernia, thereby obviating the necessity of great dissection to make an artificial tunica vaginalis.

Persistent and diligent use of the endoscope has taught us at least this—that in the urethra there are periurethral and paraurethral passages, amenable to the knife, thus once for all curtailing an attack of hitherto persistent chronic gonorrhœa. While most of us are satisfied with gradual and progressive dilatation of the urethra with sounds, or, failing in this, to resort to urethrotomy, followed by sounds, there is a small percentage of instances in which nothing short of resection and anastomosis, as planned by Koenig, will accomplish a satisfactory result.

The seminal vesicles have been attacked by the knife via the perineum for tuberculosis. It is an operation, though, of great difficulty, justified if cystoscopy shows the bladder to be intact. Without enumerating the conditions that call for the formation of a permanent suprapubic vesical fistula, we are fortunately in the possession of a very efficient method of preventing leakage of the fistula by applying the principle of Witzel used in gastrotomy. Through such a fistula it has been possible to practise cystoscopy, to learn of further progress of the disease in the bladder. When the cystoscope cannot be introduced per *vias naturales*, it has fortunately been suggested to us by Fenwick to pass the same through a large cannula employed in a preliminary suprapubic puncture.

In consequence of a more accurate knowledge of intravesical conditions incident to cystoscopy, the practice of litholapaxy and lithotrity has, and rightly so, again come in for due consideration, and it bids fair to rival the modern dictum of suprapubic cystotomy at all times. Except in such instances in which the cystoscope also shows an enlarged prostate to exist, there suprapubic cystotomy with simultaneous prostatectomy is in place.

Prostatectomy, by the perineal or suprapubic route, is still *sub judice*—seemingly a revival, as it were, of the old controversy of suprapubic *vs.* perineal section for stone.

For the galvanocautery incision of the prostate, it is the sober opinion of a growing number of surgeons, that it, too, must be accorded a place amongst the useful operations for hypertrophied prostate, and to those to whom this operation on a closed bladder does not seem surgical, Chetwood's perineal galvanocauterization is in place.

Operations on the kidneys, with the increasing applications of the cystoscope, have been greatly multiplied. Ureteral catheterization is largely responsible for this. The separate collection of the urines, free from any contamination of either side, or from the bladder, for purposes of pathological bacterial investigation, can only be accomplished by ureteral catheterization. Such examinations, however, do not in any way give us the desired information of the renal sufficiency of the kidney to be left behind, for no matter how much diseased, it is the freezing point of the urine that speaks for the propriety of a nephrectomy. This freezing point of the urine is to be studied alongside of that of the blood. Furthermore, when the freezing point of the blood itself is below the limits, it may be superfluous to catheterize the ureters at all. At this stage, a sufficient amount of information as to which is the more diseased kidney may be obtained with one of the new urine separators of Harris, Cathelin, and Luys. The dread of infecting one presumably healthy kidney when bilateral catheterization is performed is exaggerated. The tetralogy of cryoscopy, ureteral catheterization, cystoscopy, and urine separation gives us the most perfect and accurate information of the kidney function, and bids fair to still further widen our possibilities in kidney surgery.

Subarachnoid injections of cocaine for the relief and cure of functional vesical disturbances and impotence have come to us as the latest innovation.

The *x*-ray, too, has made its conquests in the recognition of vesical, renal, and ureteral calculi. These are all familiar to you. We now know that all calculi may be skiagraphed, the phosphatic with greater difficulty, to be sure; yet on the authority of Albers Shönberg, by aid of a diaphragm of lead, to shut out some of the rays of greater penetration, aided by compression of the intervening tissues, we can successfully photograph all calculi. Another refinement of skiagraphy (Wittek) for detecting renal calculi, consists in inflating the stomach and colon and even the bladder with air. These are thus rendered more refractory to the rays, and the calculus then shows by more marked contrast, being less refractory to the rays.

There is much doubt prevailing as to what constitutes a movable kidney in the pathological sense, consequently the method of nephropexy is subject to constant change. The removal of kidneys of not too large a size, without causing much disturbance of the overlying soft parts—we have hernia particularly in mind—has been rendered possible by the blunt division of the muscles as suggested by Morris. Hydronephrosis is often caused by movable kidney, and the mere anchoring of the kidney has been deemed sufficient, instead of its removal or extensive plastic work on the ureter.

The exploratory nephrotomy for hæmaturia, and the cure of this condition often incident to operation, has led to operative measures of capsule resection of the kidney for the cure of chronic nephritis. This is entirely too recent a procedure to permit of anything more than passing mention.

Tuberculosis of the kidney forms by far the largest contingent for operative interference. It has been

responsible for the great development of cystoscopy. We have learned by its aid to recognize tuberculosis of the kidney in its earliest form. At this stage there seems to be slight evidence to the effect that hygienic measures of themselves may be curative of incipient renal tuberculosis.

If not the acme of renal and vesical surgery, at least the greatest progress has been attained within the last two decades by the use of the cystoscope, and we wish (*obiter dicta*) these remarks to be a fitting tribute to the genius of Max Nitze, whose twenty-fifth year of the discovery of the cystoscope is at this hour being celebrated throughout the world.

1198 Lexington Avenue.

Lymphosarcoma of the Mesentery.—G. Candido describes a rare case of lymphosarcoma of the mesentery, with autopsy. Primitive tumors of the mesentery all belong to the connective-tissue type, while epithelial tumors result from an infection extending from the intestine. Primitive tumors include fibrolipoma and sarcoma. Sarcoma of the mesentery is quite rare. The patient was twenty-six years of age. For two months before he was seen he had complained of pain in the dorso-lumbar region extending to the sacrum, but the size of the tumor indicated a much longer duration for the growth. The pain was due to the pressure of the tumor on the solar plexus, the center of vegetative life. Compression of the stomach, intestine, abdominal sympathetic, and vagus produced loss of appetite, stercoraceous vomiting, and obstinate constipation. The urine was scanty, contained albumin, hyaline and granular casts, leucocytes and epithelial cells. There was a tumor in the abdomen which was immovable, painful, did not move with the movements of the diaphragm, and which occupied the left hypochondrium and extended up to the ensiform cartilage. The surface was hard and nodular. An exploratory incision showed that the tumor involved the mesentery close to the vertebral column, and was adherent to the stomach and duodenum. The veins, arteries, and nerves of the mesentery were compressed by it. The autopsy showed a tumor the size of the fetal head in the epigastric and mesogastric regions, adherent to the duodenum, aorta, pancreas, and vena cava. There were other smaller tumors in the mesentery corresponding to the lymphatic glands of the mesentery. The microscopical examination showed it to be a lymphosarcoma, with loose reticular connective tissue, small round cells, and a few fusiform cells. Scattered through the tumor were spots of necrosis.—*Annali di Medicina Navale.*

The Powers and Limitations of Therapeutics.—Wm. E. Quine emphasizes the fact that the subject of therapeutics is being neglected in our medical colleges. In systemic affections one of the most valuable remedies is water. Given copiously by mouth, by colonic flushings, and subcutaneously in the form of salt solution in urgent cases, water makes a decidedly favorable impression on many threatening symptoms, apparently by washing out the toxins which have been causing them. Water employed efficiently internally in systemic infections and intoxications lowers temperature, subdues delirium, promotes sleep, lessens circulatory and respiratory derangements, and conserves the strength of the patient. Apparently water accomplishes these results by acting on the cause. As to morbid anatomy, the writer states that it may be questioned whether the medicinal therapeutist, with few exceptions, has any important influence on morbid anatomy when the medicines have to act upon it through the medium of the circulation. Iodine in actinomycosis, mercury and iodine in syphilis, arsenic in squamous diseases of the skin, iodo-thyroidein in myxœdema and in cretinism, and the medicines used successfully in the treatment of inflammatory affections of mucous membranes are among the most important exceptions. But when medicines are brought to bear directly upon morbid anatomy they often affect it profoundly and determine the restoration or cure of the patient. The judicious treatment of "symptoms" is of mighty importance, and as genuinely life-saving or curative as any of the processes of surgery. No claim is made that medicines can interrupt the succession of events which constitutes the natural history of a self-limited infectious disease. But such a disease may be "cured" by medicinal and hygienic agencies in the sense of being helped by those agencies to a favorable termination which would not otherwise occur. But when an advancing process of morbid anatomy which is beyond the reach of known therapeutic influences goes so far that not enough normal anatomy is left to maintain function, even with the assistance of medicinal and hygienic remedies, the time and conditions are at hand which point to the limitations of therapeutic power.—*The Medical Standard.*

Polycythæmia of Congenital Heart Disease.—Ira S. Wile desires to urge in this affection the claims of an actual increased production of red blood-corpuscles due to the effort to bring about the oxygen equilibration of the body and proper cell nutrition. The most important congenital cardiac conditions found in congenital cardiac malformations are a patulous foramen ovale, an incomplete interventricular septum, a stenosed pulmonary orifice, and a persistent ductus arteriosus to functionate as a natural safety-valve. The usual symptoms are cyanosis, dyspnœa, and clubbed fingers. Polycythæmia may also exist without any derangement of the heart. Stengel believed not in an absolute polycythæmia to furnish greater oxidizing surface, but in a relative increase of corpuscles due to stagnation and inspissation of the blood. As to polycythæmia and corpuscular longevity, with the rate of corpuscular production constant and the length of corpuscular life increased, polycythæmia naturally follows. According to Arcangeli, with deficient amount of blood going to the lungs in cases of pulmonary stenosis, there is insufficient oxidation. This lack of oxygen stimulates the hæmatopoietic tissues to productive activity with cyanosis and polycythæmia as a result. The greater the polycythæmia, the worse the prognosis. It has been observed that in chronic heart disease, with continued slight inadequacy of circulation, there is often polycythæmia. In congenital heart disease the polycythæmia is said to be due to a disturbed distribution of the corpuscles. There are three methods of increasing oxygen available to the body cells: (1) To increase the power of the cell to carry oxygen is impossible, because of the limitation of this ability to the single iron atom of the hæmoglobin. If the total amount of hæmoglobin per corpuscle were increased, the weight and bulk of the blood per cubic millimeter would be greatly increased even if the number of corpuscles were to remain stationary. With pulmonary stenosis only a portion could be aerated out of each mass, leaving the congested venous heart; oxygen equilibrium could not be maintained. (2) Attempts at more rapid aeration by increased heart action show themselves on exertion, but the increased demands upon the myocardium soon bring about its weakening and power of compensation is lost. (3) To increase the number of red corpuscles without greatly altering the actual quantitative mass of blood propelled through the lungs does not offer any difficulties. It offers the solution to the problem of suboxidation and cell starvation without too great a strain upon the heart itself. The writer believes that in the polycythæmia of congenital heart disease we have an excellent example of "compensatory hypertrophy." The number of red corpuscles is increased in order to secure the necessary amount of oxygen for the proper nutrition and development of the various cells of the body. The polycythæmia of congenital heart disease is to be regarded as an actual and compensatory increase in the number of red blood-corpuscles.—*Archives of Pediatrics.*

FLIES AS DISSEMINATORS OF TYPHOID FEVER.

CONSIDERING the amount we now know as to the rôle of the mosquito in the transmission of disease, it is surprising how comparatively little we know concerning the similar activity of the much more omnipresent fly. Yet there can, *a priori*, be little doubt that that insect must distribute very many things that we know not of, as it is everywhere and into everything. These considerations lend special interest to the paper by E. E. Austen in the *Journal of the Royal Army Medical Corps* for June, which is in the nature of a review of our present knowledge of the subject. Of insects which directly or indirectly affect the welfare of man and the domestic animals, the vast majority belong to the order *Diptera*. Apart from the vast army of bloodsucking forms (midges, mosquitos, buffalo gnats, horse flies, and tsetse flies), other forms in the larval state affect man, horses, and cattle, as subcutaneous or intestinal parasites. Other forms (of which the house fly is a notable instance) eat of and pollute man's food and drink. In an order so closely associated with man, it is not surprising that many species should carry microorganisms to him, either directly into his blood at the moment of puncture, or, in the case of the non-sanguineous forms, merely mechanically. The action of flies is of the latter character. In intestinal diseases due to micro-organisms, for example cholera (in which disease the evidence as to diffusion by flies is regarded by Nuttall as "absolutely convincing") and typhoid fever, the danger lies in the overwhelming attraction for these insects of fecal matter. The commission which investigated the typhoid epidemic in our camps in the Spanish war, found the water supply good and not accountable for the outbreak, which in its opinion, the commission's opinion, was due to the agency of the flies which swarmed in all the camps and devoted their attentions impartially and alternately between the open, undisinfected latrines and the hard tack and "sow belly" eaten by the troops. Dr. M. A. Veeder reports having seen fecal matter in shallow, open trenches, with the merest apology for disinfection, and only lightly covered with earth at intervals of a day or two. The matters, fresh from the bowels, were covered with flies, while only a short distance away was an eating and cooking tent. To say that the flies were busy traveling back and forth was putting it mildly. This state of things was reproduced in many a British camp during the Boer war, of which the author gives several instances. Drs. H. H. Tooth and J. E. C. Calverley also note the interesting fact that it is almost possible to diagnose the typhoid-fever patients in a tent among a number of men apparently equally ill, by the partiality of flies for them, and they found that when such a patient put out his tongue flies would settle on it. At Bloemfontein flies were a perfect pest, everywhere and on everything, and it was impossible not to regard them as important disseminators of typhoid-fever, all the more as in South Africa the disease practically ceases when the cold and often frosty nights put the flies out of commission, though the days after 10 A.M. are as hot as an English summer (often 80°; rarely below 70°). Munson ("Military Hygiene," 1901) says: "Among troops in camps during warm weather the use of food contaminated with typhoid bacilli, brought from the latrines by means of flies, is a factor of the greatest importance in spreading the disease. Numerous observers have demonstrated the presence of the specific bacillus in the excrement of flies made to feed on infected material, and colonies of typhoid bacilli have been shown to develop in the tracks of flies which had been allowed to settle on typhoid discharges, and then made to walk over a suitable solid culture medium. Vaughan states that during 1898, in some of the large military camps, where lime had recently been sprinkled over the contents of the latrines, flies with their feet whitened with lime were seen walking over the food. He also noted that officers whose mess-tents were protected by means of screens suffered proportionally less from typhoid fever than did those whose tents were not so protected." . . . "The typhoid epidemics of 1898 gradually decreased with the approach of cold weather and the disabling of the fly as a carrier of the infection."

So much for the field observations. On the experimental side, Celli, in 1888, fed flies with pure cultures of the *Bacillus typhi abdominalis*, and examined their intestinal contents and dejections, microscopically and culturally. Inoculations of animals proved the bacilli which passed through the flies to be virulent. Also from their experiments, Lieut-Col. R. H. Firth and Major Horrocks conclude that ordinary house flies can convey infective matter from typhoid excreta or other polluted material to objects on which they may rest, walk, or feed. Such infective matter appears to be attached not only to their heads, but also to their legs, wings, and bodies. It has not, they consider, been proved that the typhoid bacillus passes through the digestive tract of the fly.

There is yet another possible mode in which flies infesting a latrine may be dangerous, even though they never leave the spot. An old idea of some Anglo-Indian surgeons was that dysentery could be caught by using the same latrine as a dysentery patient. There may be something in this. Experiments on animals have shown that the disease can be inoculated per rectum. Austen adds that this suggests the equal possibility of infection *in situ* by typhoid bacilli via flies infesting latrines used by incipient or ambulant enteric patients. In his opinion, many cases of intestinal myiasis at home (due to the larvæ of flies of the genus *Homalomyia*) are probably traceable to

oviposition by the parent flies on the anus during the use of some country privy, where the flies are common.

The author concludes by asking, what is the practical outcome? Most authors who have hitherto touched upon the matter have contented themselves with insisting upon the necessity of promptly burying all refuse, horse droppings, offal, etc., in which flies might breed, the regular disinfection of latrines, and the covering of their contents with earth. All such precautions, well enough in their way, seem, however, to Austen a little beside the mark. What is wanted is some simple but effective means, adapted to service conditions, and capable of preventing flies from gaining access to the contents of latrines at all, for however short a time, for the mischief may be done in a very short time. Smith maintains that the orthodox latrine-trench system, thoroughly carried out, is the best system known, but it is only by constant, wearying supervision that any approach to efficiency can be maintained, which at best amounts only to half-hourly covering up and liming. Austen then says that theoretically a spray apparatus, distributing lime or sulphate of iron solution, might work, but would probably be liable to get out of order and would inevitably fail, sooner or later, for want of water if for no other reason. He thinks that the best chance is offered by a system of light metal covers for the latrines, provided with apertures at regular intervals, closed by spring flaps and moved by the feet, together with the discharge at intervals into the trench of some such fluid as crude kerosene, which would probably render the latrine contents less attractive to flies.

TUBERCULOSIS IN BIRDS.

The *Journal of Medical Research* contains an article by V. A. Moore on this subject, in which the actually reported and positively diagnosed cases are very few. Pernot reported six outbreaks occurring in Oregon in 1899. The bacilli were present in "countless numbers" in the fæces, in the advanced stages of the disease. Besides reports by authors of other less unequivocal cases, Moore and Ward reported the disease in California in 1903; tubercle bacteria were found in the tissues and pure cultures obtained.

From his own studies, and those of former writers, we find that tuberculosis varies in its manifestations quite as much in the feathered tribes as it does in man and the higher of the brute creation. From the descriptions it appears that the lesions in fowls usually manifest themselves especially in the liver, spleen, and intestines; also in the mesentery, skin, and joints, although other organs are sometimes involved. The dependent or secondary changes were marked emaciation, often resulting in the complete atrophy of certain muscles, especially in the pectoral region; and anæmia, the number of red corpuscles in advanced cases falling to 1,100,000. There was a slight increase in the leucocytes, especially in the polynuclear forms. The hæmoglobin ran from 35 to 70 per cent. (by Gower's test). The temperature ranged from 102.7° to 108.5° F. In the case in which the temperature was only 102.7° F., the disease was found post-mortem to be very advanced, so that the low temperature may be considered as a terminal subnormal.

From the anatomical side, the essential difference between the structure of tubercles in fowls and in higher mammals is the distinctness of the zone between the epithelioid and giant cell band and the reactionary zone. This difference, however, is not strikingly different from the structure of tubercles in certain of the smaller mammals, especially the carnivora. There is a larger number of giant cells than I have observed in mammals, and there seems to be a stronger tendency for the lesions to spread by continuity.

In cover-glass preparations from tubercles in the liver, spleen, and kidneys, tubercle bacteria are readily found, usually in very large numbers. They resemble quite closely those of the human and bovine varieties in their size and general morphology as they are found in the tissues of the fowl. They often appear in dense masses. Chains made up of a number of short elements are rarely present.

The feeding and inoculation experiments so far made have taken two natural directions, namely that of endeavoring to infect other animals with the avian microorganism, and, conversely, to infect fowls with the human and bovine bacillus. As regards the infection of other animals by the avian form, all observers are agreed that it will produce generalized tuberculosis in other fowls, and in finding nearly constant fatal results following upon the inoculation of rabbits. With regard to guinea-pigs, so uniformly susceptible to the human tubercle bacillus, the evidence is, however, conflicting, a number of investigators producing local lesions only. But Garino inoculated ten guinea-pigs subcutaneously, and twenty-five intraabdominally; the latter emaciated and died in from twenty-eight to forty days, while the former developed local lesions only, which eventually healed with recovery of the animal. Cadiot made the interesting observation that guinea-pigs inoculated with tubercle bacilli derived from parrots developed tuberculosis as though inoculated with the human form of the bacillus. Both he and Fröhner mention the frequency of tuberculosis in parrots and suggest its probable origin from human attendants.

The same conflict of experience obtains with reference to the infection of fowls by the tubercle bacillus of other animals, Nocard, Johne and others reporting positive results, while Ribbert, Strauss and Wir Wortz, Sibley, and Moore failed to obtain results after prolonged trials.

The observations already made suggest that the infection takes place through the digestive tract, and that the virus is eliminated from the diseased birds with the excreta. The method of its dissemination, therefore, after it has been once introduced into a flock is not hard to suggest. It is more difficult to explain how the disease was introduced, but the introduction of tuberculous fowls, however, seems at the present time to be the most likely source.

The differential diagnosis has been referred to as being somewhat difficult in living fowls. The tuberculin test, reported to be of value, failed in my hands as a reliable indicator. Tuberculin made from the avian organism has since been tried by Dr. Ward, also with negative results. In the light of

these facts, the question of how to eliminate a few score of diseased birds from infected flocks containing from a few hundred to several thousand fowls each is not an easy one to answer.

The Treatment of Nephritis by Decapsulation of the Kidney.

While there can be no doubt as to the validity of the evidence that marked improvement, both in the urinary symptoms and in the general condition, has followed the operation of decapsulation of the kidney for the relief of chronic nephritis, there has been considerable difference of opinion as to the manner in which such a result is brought about. It is contended by the advocates of the operation that in sequence of the removal of the capsule of the kidney, with the attendant manipulation and irritation, an increased supply of blood is sent to the kidney, through the formation of new vessels as a result of the reparative proliferative process. That this explanation is not the correct one has been shown by histological studies of kidneys whose capsules had been removed both clinically in man as a therapeutic procedure and also experimentally in animals. Some interesting observations in this connection have recently been recorded by Dr. I. Walker Hall and Dr. G. Herxheimer (*British Medical Journal*, April 9, 1904). These investigators found that when in rabbits the capsule was removed from healthy kidneys it re-formed early, being represented in from ten to twenty-one days by a fibrous covering thicker than the original. No marked formation of new blood-channels was found, however, between the kidney and the surrounding tissues to which it was adherent. When decapsulation of the kidney was practised after the development artificially of an acute degenerative nephritis, it was found that when distinct adhesions formed small arteries and veins were present in the tissues immediately surrounding the kidney, but these were always separated from the cortex by the thick, newly formed capsule. Neither was there any evidence that the capillaries passing from the capsule into the cortex were more numerous than those that are present normally. Changes of a comparable character were observed further in two human kidneys, one of which had been incised for the removal of a calculus, and of the other the posterior portion of the capsule had been removed in order that the organ might become adherent and fixed to adjacent structures.

The histological conditions, therefore, fail to explain the occasional success of the operation of decapsulation of the kidneys for chronic nephritis; on the contrary it would seem as though the necessary traumatism and the subsequent changes would rather tend to aggravate the inflammation of the kidney. That the augmented discharge of urine and the increased elimination of urea and the disappearance of albumin and tube-casts after the operation are not due to mere relief of congestion is shown by the fact that intense hyperæmia was found after the capsule had re-formed. If the improvement be due to an influence exerted on the sympathetic ganglia entire denudation of the renal cortex would scarcely seem to be necessary, and it might with advantage be replaced by puncture or longitudinal and transverse incision of the kidney.

An Experiment in Medical Latin.

The question of a universal, or rather an international, language is one that is constantly recurring in one form or another and yet makes little or no progress toward a satisfactory conclusion. Every little while a new language is devised to meet the requirements of international correspondence. Many of these are ingeniously contrived, and almost every one, from Volapük down to the latest invention of an Italian who has thought out a grammarless Latin, would answer the purpose admirably if it only had life. They have the form, but not the essence, and resemble living speech about as much as does Peewit, the artificial face, resemble the speaking human countenance instinct with soul. Many real languages have also been presented to the suffrages of the world for adoption as the medium of international exchange. The Medical Record has done its part, and several years ago suggested the adoption of Modern Greek as the official language of medicine; many and cogent reasons were offered why this proposal should be accepted, but the returns to date show that our arguments made but one convert. We fear the world must wait a little longer until English becomes, without urging but naturally and through the irresistible force of destiny, the true lingua franca.

In the meanwhile what may be called a universal registration language is a necessity; every science, whether medicine or botany or linguistics, must have some universal medium for recording the essence of things in simple style and compact form. In medicine Latin always has and probably always will answer this purpose in a more or less satisfactory way. The language has been so employed in records of diagnosis and of pathological findings, especially in European universities, and there is no reason why its use in medicine should not be still further extended.

An interesting experiment in this line has been made in "Studies from the Department of Neurology" of Cornell University, recently published under the direction of Dr. C. L. Dana, in which each article is preceded by an abstract in Latin. The following is one of these epitomes, and we think hardly anyone, acquainted with the ordinary language of medicine and with anatomical nomenclature, could fail to grasp the sense of it even if unable to give a literal translation:

Apoplexia Iuvenilis, cum Autopsia. Auctore J. R. Hunt. Descriptio casus gravis, fatalis hæmorrhagiæ cerebri viri iuvenis viginti et unius annorum. Impetus erat subitaneus, coma profundum, cum hemiplegia sinistra. Oculorum iugata ad dextrum deviatio. Mors intra sex dies. Autopsia exhibebat copiosam hæmorrhagiam in recta hemisphæra cerebri in capsula interna et in ganglio basali. Arteriæ erant incrassatæ et atheromaticæ velut senum. Aderat hypertrophe cordis, myocarditis, atque nephritis parenchymatosa. Quod in hoc casu plurimum interest, extraordinaria degeneratio vascularia est in viro tam iuveni.

Such an abstract would surely be understood by an educated physician, whether he were French, German, Russian, or Japanese, and he could tell after reading it whether or not it would be worth his while to have the article translated for more careful study. We understand that a similar plan has been adopted in the volume of transactions of one of the London societies, and others might well follow this lead.

Substitution of a Piece of Ivory for the Whole Diaphysis of the Radius.—Karl Vogel describes the case of a child in whom the diaphysis of the radius was destroyed but the periosteum remained. A piece of ivory was substituted, and at the end of a year this showed a new subperiosteal growth of the epiphysis as well as of the diaphysis.—*Deutsche medizinische Wochenschrift.*

News of the Week.

Death of a Noted Sanitarian.—Sir John Simon, K.C.B., former president of the Royal College of Surgeons and of the Royal Society, died in London July 23. He was born in London in 1816, educated at Greenwich, and later at King's College in medicine and surgery. He devoted his best efforts to sanitary reform. He drained the city of London, abolished cesspools, and pointed out the true moral of the cholera visitations of 1845 and 1855. For twenty-one years he held the post of central medical officer, and during that time presented a series of invaluable reports to the Privy Council. One of the most important of them was the defence of vaccination. Sir John was the author of many books on miscellaneous subjects. He was a member of many medical and scientific associations. British and European universities honored him with degrees, and Queen Victoria made him a K.C.B. on the occasion of her first jubilee in 1887.

Discouraging to Promoters of Cleanliness.—After having expended over $80,000 in constructing a public bath in William H. Seward Park for the benefit of the people of the lower East Side, the Park Department has been compelled to close it because defects found in the construction of the baths after they were put in operation render them insanitary and practically useless. The baths opened on July 1, and four days later they closed their doors to the people. Since then they have not been used at all. Through ignorance and carelessness or malicious mischief, the people who have used the baths have damaged much of the mechanism. The baths are divided into a number of compartments, in each of which is a shower controlled by cocks operated by the bather. In many cases these cocks have been wrenched off, and the pipes to which they are connected have been pulled out of place, and in some instances cut. Moreover, when the baths were built, it is said, insufficient provision was made for the carrying off of the water that was used. Small drains were installed, which, when there were many bathers, soon became choked, and the water overflowed into the basement and the engine room, where it threatened to put out the fires that supplied the warm water for the baths. To remedy this defect all the present drains will have to be removed, which will necessitate the tearing out of a good part of the interior of the building.

Suits against Delinquent Milk-Dealers.—Suits against 314 delinquent Chicago milk-dealers were successfully prosecuted during the past week. The highest penalties, $50 and costs, were inflicted on two classes of offenders—those selling the low grade milk after warming, and those found guilty of using preservatives.

Serum Treatment of Leprosy.—Dr. E. R. Rost, I.M.S., is reported to have prepared a specific remedy for leprosy, similar in its mode of elaboration to tuberculin, which he calls leprolin. At the present time over one hundred cases of leprosy are now being treated in Burma by injections of leprolin, and the treatment is also being tried in other places in India. Dr. Rost claims that four of the one hundred patients treated in Rangoon have been cured, and in the great majority of those still under treatment the improvement is marked. Rich cultures of the lepra bacillus, for the preparation of leprolin, are obtained from bouillon deprived of its sodium chloride and other salts.

A Cancer Hospital for Philadelphia.—At a meeting of physicians and philanthropists held in Philadelphia on July 21 plans were formulated for the founding of a cancer hospital of national scope. The proposed institution is to be known by the dreadful name of the "American Oncologic Hospital," and application will shortly be made for a charter of incorporation. A temporary organization has been formed and a site for a building is being looked for. The hospital is to be devoted exclusively to the treatment of new growths and to scientific investigation into the causes underlying the recent increase in the prevalence of cancer. Every means that promises success in treatment will be employed, including especially electricity, the *x*-ray, and radium.

A Mild War on Patent Medicines.—The recent showing by the editor of *The Ladies' Home Journal*. of the enormous proportion of alcohol contained in many of the popular tonics, nerve restorers, and other well advertised patent medicines, has at last roused the temperance people to action, or at least to words. At the annual meeting of the National Temperance Society, held at Ocean Grove, N. J., last week, resolutions were adopted calling upon the Board of Managers of the society to memorialize Congress not to issue any patent or proprietary rights to any one for any remedy, medicine, "cure," or other compound containing alcohol, opium, or other narcotic drug, and to make it obligatory that all proprietary or patent medicines shall be put up in bottle or package with a label on which are printed the ingredients of the preparation. Another petition to Congress was decided upon memorializing that body to appoint a licensed chemist in each state to analyze all proprietary preparations, so that the sale of medicines which contain spirits may be prohibited.

The Mule in the Army Medical Department.—The *Tribune* says that army medical officers will make important tests in medical supplies transportation in course of the joint manœuvres of the army and militia in September at Manassas, Va. They contemplate the employment of the army mule as a means of getting to the firing line the supplies for the first dressing station. Hitherto these supplies have been carried in ambulances, but of course that vehicle cannot break into columns of troops, and there are places in a rough country where troops are apt to be operating that the ambulances cannot go. In the Santiago campaign there was great difficulty in transporting these supplies, and about the only means of getting them to the front was on the backs of the hospital corps men. This, of course, was unsatisfactory, and operated as a hardship to the hospital stewards. It is believed that the army mule can go wherever troops are stationed, and this facility will add to the efficiency of the medical department in the field.

The American Association of Obstetricians and Gynecologists will hold its seventeenth annual meeting at the Hotel Monticello, St. Louis, Tuesday, Wednesday, Thursday, and Friday, September 13, 14, 15, and 16, 1904, under the following administration: *President*, Walter Blackburn Dorsett of St. Louis.; *Vice-Presidents*, Aaron B. Miller of Syracuse and William D. Haggard of Nashville; *Secretary*, William Warren Potter of Buffalo; *Treasurer*, Xavier O. Werder of Pittsburg; *Executive Council*, Edwin Ricketts, Walter B. Chase, A. Van der Veer, Lewis S. McMurtry, L. H. Dunning, and Rufus B. Hall. The preliminary program contains the titles of twenty-five papers, including the president's address.

The Rocky Mountain Interstate Medical Association will hold its sixth annual meeting at Denver, on September 6 and 7, under the presidency of Dr. H. D. Niles of Salt Lake. The corresponding sec-

retary is Dr. George A. Moleen of Denver. The territory represented by the membership in its society includes the States of Arizona, Colorado, Idaho, Montana, New Mexico, Utah, and Wyoming.

The Mississippi Valley Medical Association will hold its annual meeting in Cincinnati on October 11, 12, and 13, at the Grand Hotel, under the presidency of Dr. Hugh T. Patrick of Chicago. The secretary of the association is Dr. Henry Enos Tuley, 111 W. Kentucky Street, Louisville, Ky. The executive committee is composed of Drs. B. M. Ricketts, chairman, H. J. Whitacre, and M. L. Heidingsfeld, of Cincinnati.

Typhoid Fever in the Mediterranean Station.—Six officers and two sailors on the *Kearsarge*, of the Mediterranean squadron, were recently taken ill with typhoid fever nearly simultaneously while at Triste. The cases were light, and Rear-Admiral Barber reports that all the patients are now doing well. The disease has been traced to some ice obtained for the ward-room mess at the Piræus, the ice-machine on the vessel having broken down.

Army Dental Surgeons.—At the annual meeting of the New Jersey Dental Association, held last week at Asbury Park, a resolution was adopted calling for the creation by Congress of a commissioned corps of dental surgeons, who shall hold rank corresponding to the rules governing the medical department of the regular army.

Death of a Noted Russian Writer and Physician.—Antoin Chechoff died at Badenweiler, Germany, on July 15. He was a physician, but his reputation throughout Russia was as a literary man. He was one of the nine Russian academicians and was considered the Du Maupassant of Russia, ranking higher as an artist of the pen than Gorky. His death was a result of consumption. Only a few weeks ago M. Chechoff volunteered to go to the front in the Far East as an army surgeon, but his illness made it impossible for the military authorities to accept his services.

The State Medical Society of Wisconsin.—At the annual meeting of this society, held in Milwaukee the latter part of June, the following officers were elected: *President*, C. W. Oviatt of Oskosh; *Vice-Presidents*, J. A. L. Bradfield of La Crosse, Gilbert E. Seaman of Milwaukee, and A. B. Rosenberry of Wausau; *Secretary*, Chas. E. Sheldon of Madison; *Treasurer*, S. S. Hall of Ripon. The next annual meeting will be held at La Crosse in June, 1905.

Dinner to Dr. Earles.—A dinner was given in honor of Dr. W. H. Earles of Milwaukee, Wis., on July 16. Dr. Wm. A. Evans of Chicago acted as toastmaster. Toasts were responded to by Rev. P. Fitzgerald, Mr. J. Emil Bench, Mr. John L. O'Connor, Dr. M. H. Fisk, Dr. Truman W. Brophy, Prof. R. W. Sommer, Dr. G. Kletsch, Hon. David S. Rose, Mayor of Milwaukee, Dr. John B. Murphy of Chicago.

The Fourth Austrian Balneological Congress will meet at Abbazia, October 12–16, 1904, under the presidency of Professor Winternitz of Vienna.

A New Genitourinary Journal.—The announcement is made that the first number of *The American Journal of Urology* will appear in October. It will be the official organ of the American Urological Association. The editor will be Dr. Henry G. Spooner of New York City. The journal will be published by the Grafton Press.

One of the Tri-State Medical Societies.—At the annual meeting, in St. Louis in the middle of June, of the Tri-State Medical Association of Missouri, Illinois, and Iowa, the following officers were elected: *President*, Francis Reder of St. Louis; *Vice-Presidents*, Daniel O'Doherty of Cherokee, Iowa, and J. T. White of Freeport, Ill.; *Secretary*, E. O. Sisson of Keokuk; *Treasurer*, Emory Lanphear of St. Louis. The next meeting will be held at Keokuk in April, 1905.

Dr. Wm. Litterer has been elected professor of histology, pathology, and bacteriology in the medical department of Vanderbilt University, Nashville, to succeed Dr. Louis Leroy, resigned.

The Sioux Valley Medical Association.—At the annual meeting of this society, held June 22 and 23 at Sioux Falls, S. D., the following officers were elected: *President*, M. Sullivan of Adrain, Minn.; *Vice-Presidents*, A. E. Cook of Randolph, Neb., and R. E Woodworth of Sioux Falls, S. D.; *Secretary*, M. E. Silver of Sioux City, Iowa; *Treasurer*, S. A. Brown of Sioux Falls, S. D.

Rest Cure for City Consumptives.—Health Commissioner Darlington is planning to give New York a "rest cure" for consumptives on North Brother Island. In the *City Record* he advertised for bids on the contract for the building required.

Low June Mortality for Chicago.—It is announced by the Chicago Board of Health Bulletin that during the month of June there were 1,745 deaths at all ages reported—an annual rate of 11.01 per 1,000 of the population, and 24 per cent. less than the average June rate of the previous decade, which was 14.52. Of this total there were 430 under five years of age, or less than one-fourth (24.6 per cent.). Ten years ago (1894) there were 2,033 deaths at all ages in the month of June, of which number 959 were under five years of age—a proportion of nearly double (47.1 per cent.) that of June, 1904.

Dr. Burtis Burr Breese of the Tennessee University has been appointed professor of psychology at the University of Cincinnati, at a salary of $2,500 a year. He was recommended by the new president, Dr. Chas. W. Dabney.

Christian Scientists and Osteopaths.—City Solicitor Scott of Cincinnati has rendered an opinion on the question as to whether the signature of a Christian Scientist or an osteopathist to a death certificate was to be regarded as equivalent to that of a recognized physician. He informed the Health Department that, inasmuch as Christian Scientists and osteopathists are not recognized by the courts and statutes as legal practitioners, and inasmuch as they profess no knowledge of medicine, their opinion as to the cause of death can be of little value to the officials. Their signatures, therefore, signify no more than those of other laymen. In such cases the coroner must be called to determine the cause of death.

Increase of Phthisis in Indiana.—The State Board of Health has just issued a bulletin showing an alarming increase in consumption in Indiana. During the month of June the deaths from this disease numbered 365, an increase of 57 over the preceding month. The board says something must be done, and it will use these and other statistics to press the demand for legislation looking to the control of the disease.

Typhoid Fever on the Increase in Cincinnati.—Sixty new cases of typhoid fever were reported to the Health Department of Cincinnati last week, and in one ward of the City Hospital, containing fifty patients, there are twenty-four with typhoid fever.

A New Emergency Hospital Needed.—Dr. S. G. Cook, president of the board of police surgeons, has written to Police Commissioner McAdoo suggesting the establisement of a new emergency hospital in the vicinity of the Oak street police station. For many years there has been need of better hospital service east of Broadway and below Canal street.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

ROYAL CEREMONY AT ST. BARTHOLOMEW'S HOSPITAL—BERIBERI AND POLITICS—CAVENDISH LECTURE BY PROFESSOR MIKULICZ—RADECKI-FORTUNE FOR CHARITIES—DR. BARTON AND HIS AIR-SHIP ACCIDENT

LONDON, July 8, 1904.

THE King and Queen, with the Prince and Princess of Wales, went into the city on Wednesday, and His Majesty laid the foundation stone of the new wing to St. Bartholomew's Hospital. The Prince pointed out in the address he presented to the King that the demands on the work of the hospital have far outgrown its accommodation. The new building is the first instalment of what is to be undertaken. Its site is part of the land purchased from Christ's Hospital, and is to contain out-patients' and casualty departments, as well as the special departments and accommodation for resident medical officers and other necessary rooms. His Majesty was president of the hospital for thirty-four years, and on his accession handed on the office to his son. Sir Trevor Lawrence, the treasurer, had the pleasure of receiving the intimation that the King would give £1,000 to the building fund. A check for this amount was received yesterday, and another for £500 from the Prince of Wales. For the ceremony of the day a spacious pavilion holding three thousand persons had been erected, and three thousand filled it. Among the brilliant assembly the medical staff of the hospital and other representatives of the profession had places. The King, having laid the stone in the workmanlike manner in which his long practice makes him expert, a quaint ceremony of olden time was then performed. This was the investing and "charging" the Queen as a governor of the hospital. The ancient form may interest readers. Sir T. Lawrence inquired whether it was Her Majesty's pleasure to "receive her charge as governor" as the first lady elected a governor and the first donor to the building fund. The Queen bowed assent. "Then," said Sir Trevor "I will ask the clerk to read the charge in accordance with ancient custom." Then the clerk recited the following ritual:

"Your Majesty, having been elected and chosen a governor of St. Bartholomew's Hospital, it is your duty and charge to acquit yourself in that office with all faithfulness and sincerity; endeavoring that the affairs and business of the said hospital may be well ordered and managed, and promoting the weal and advantage of the poor wounded, sick, maimed, diseased persons harbored in the said hospital. To this end Your Majesty is now admitted a governor of St. Bartholomew's Hospital." The Queen again bowed assent and Sir Trevor handed her a miniature governor's staff enclosed in a case, observing that though less than the ordinary size it was no less effective as an emblem of authority.

In the House of Commons, among other attempts to make political capital, a good deal of nonsense has been talked about beriberi, of which cases have appeared in South Africa With the intention of worrying the government, question after question has been put, and it was necessary to telegraph to Lord Milner, who replied by the same, that three deaths had occurred on board a vessel at sea and five after landing at Durban. The ship was sent back to China with the remaining cases. The medical officers did not regard the disease as seriously threatening the colony. On Tuesday the subject was followed up by Dr. Hutchinson, but entirely as a party move. Another member talked of it as a loathsome, dangerous disease, and wanted to know what penalties were inflicted on the vessel. He was told that the Natal government had replied to the question that it was the custom of the colony to inflict punishment after—but not before—the law had been broken, and there was no breach in this case. Another member said Sir P. Manson, in October, 1897, had said beriberi was common in the port of London among Lascars from the East, and he wanted to know the number of cases treated in the Seamen's Hospital annually. The government procured him the information, viz., an average of twenty-four per year in the decade ending 1900. To this reply was added that the Medical Officer of the Port did not regard it as infectious in the ordinary sense and considered no special precautions necessary. The newspapers have taken up the matter, but solely for the purpose, on the one hand, of embarrassing the government and on the other hand of defending it. So of the discussion nothing of medical value can be expected.

The Cavendish Lecture this year was delivered on the 24th ult., by Prof. J von Mikulicz-Radecki of the University of Breslau. He devoted it to an account of "experiments on the immunization against infection of operation wounds, especially of the peritoneum." He dealt chiefly with the efforts to increase the resistance of the body to bacterial invasions. At the present time this is the only way of diminishing the danger of peritonitis, and one way of effecting this is by producing an artificial hyperleucocytosis. Referring to the work of Loewy, Richter, and Jakob, he said their experiments proved that animals had been made immune to pneumococci and mouse-septicæmia.

Then Hahn showed that during the stage of hyperleucocytosis the blood of dogs and men possessed a higher bactericidal value than normal blood. Hahn used nuclein in his experiments on dogs, and tuberculin in those on men. More recently Hofbauer obtained favorable results in puerperal septicæmia by administering nuclein by the mouth. The slight results obtained by artificial hyperleucocytosis, *e.g.* in pneumonia, the professor attributed to the organism being overpowered before the remedy was used. The natural defences had been used up and a further increase could not be expected. But the experiments suggest the possibility of successful prevention by this method. Salieri had already shown that the natural resistance of guinea-pigs could be increased by normal saline solution, and he tried the plan on cases of laparotomy. Before then, Issaeff had obtained increased resistance to cholera by nucleic acid. The lecturer then stated results at Breslau. By injecting into the peritoneum or under the skin nucleic acid and some other substances great increase of the white cells was obtained. By careful management the resistance of the peritoneum could be raised to forty times the normal. It was found that by this preventive method the resistance could be so raised that a quantity of intestinal contents could be placed in the animal's peritoneal cavity without causing damage. This opens a new field for the surgeon in preventing post-operative peritonitis. In man fifty-eight cases have been treated and no serious symptoms noticed—only a local reaction for a day and a slight rise in temperature. The results have satisfied the lecturer, and he gave as full details respecting them as could be given in a lecture. Decinormal saline solution increases leucocytosis, and Professor Mikulicz stated that he had also used more and more, during the last two years, free irrigation of the peritoneal cavity with warm saline solution in all laparotomies in which the peritoneum runs some risk of infection.

Lord Goschen distributed the prizes at Guy's Hospital on Wednesday, and said that thirty-four years ago he had a great deal to do with hospitals for the poor and was interested in the great advances made since in medical science. He asked the students what dreams they were dreaming—practice, fame, bed-side, or laboratory work? and told them the nation wanted men of research to open the mysterious winterland of the explored provinces of medical science. But all students could not be specialists, and so hospitals must send out the army of general practitioners. He would be sorry to see the family doctor disappear. Whatever famous dentist came to town he preferred to go to the one to whom every tooth in his head was an intimate friend. In their serious work he commended to them gentleness, sympathy, and honesty.

Mr. George Handyside of Newcastle has bequeathed £20,000 to the Newcastle Infirmary, and other legacies to charities, making a total of £92,000. His estate is valued at £147,860.

Dr. Barton, who, for the last year or more, has been engaged in constructing an air-ship, met with an accident on July 4 through an explosion of the gas preparing for the balloon. Several wounds about his face and head laid him aside, but it is hoped he will be about again in another week.

POST-GRADUATE MEDICAL STUDY IN PARIS AND IN BERLIN.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR: Having spent considerable time in Paris and in Berlin, I can give an estimate of the comparative merits of the two cities as centers for post-graduate medical study.

As far as I saw, very few Americans go to Paris for post-graduate medical study; they usually flock to Berlin or to Vienna. Any medical man, however, going abroad who possesses a little knowledge of French, misses a great deal by not stopping in Paris. But when it is a question of choosing either the one or the other, I must say at the outset that Berlin should be given the preference for reasons soon to be stated. I do not speak of Vienna, not having had personal experience with that city. In order to make the subject intelligible I think it will be of interest to say a few words in regard to medical matters in general in the two mentioned cities. I do not say France and Germany, because Paris and Berlin are practically the two cities in these two countries which come into consideration in this respect.

The hospitals in Paris are numerous; some of them, as is well known, are of historic fame, both from a medical

standpoint and in many other regards, and most of them are government institutions. The hospitals supported by private charitable organizations, though some of them are big institutions, are not very popular among the French people, nor are they looked upon with much respect by the medical profession. Very few famous men, especially of the university staff, are connected with private hospitals in Paris. The government hospitals can be freely visited by any medical man during the time of *service*—that is, when the hospital physicians are making the rounds of the patients, which is always in the morning between nine and eleven o'clock.

In this connection I may make some remarks concerning the hospital arrangements in Paris. The medical men attached to the hospitals consist of externes, internes, and chiefs. The term of service of the externe is three years, and he lives outside; the interne is the resident physician or surgeon, and his term is four years; the chief has a life position. There are small salaries attached to each of these positions. All appointments, including that of chief, are made after competitive examinations, and only a Frenchman, native or naturalized, can be appointed.

Each chief of a hospital has under him only about two wards—a male and a female ward. Occasionally one may have a whole pavilion consisting of four wards; but this is an exception. Each chief has an externe and interne, and a staff of nurses, and he is responsible for his two wards. There is no such a title as a consultant to a hospital, as each chief is supposed to know his business and is supposed to visit daily his wards, except on holidays and when on vacation.

Thus it will be seen that in every hospital there are as many chiefs as there are male and female wards; this consequently gives an opportunity to many physicians to be connected with the hospitals. Most of the hospitals have well-equipped laboratories where good scientific work is being done. The chief professors of the university deliver clinical lectures twice a week at the amphitheaters of the hospitals. Some of them never lecture at the college buildings at all, but do all their teaching in their respective hospitals. The professors themselves usually have only two wards in the hospitals to which they are attached.

As I said above, one can freely visit the hospitals of Paris and see all the work that is being done there.

Courses during the vacations are given to physicians in the several laboratories of the university and the hospitals under the auspices of the respective professors. These courses must be paid for, but if any physician, French or foreign, wishes to do some original work in any of the laboratories of Paris he has little difficulty in getting in. From this brief description it will be seen that Paris is a large field for post-graduate study. How it compares with Berlin will be seen from the following lines: I must not omit a brief mention of the Dupuytreu museum. It contains an immense collection of pathological specimens in all the fields of medicine. I do not think there is anything like it anywhere else. A visit to this museum alone, which is connected with the medical college buildings, will repay a medical man for his trouble in going to Paris.

Things are different in Germany, and by this I mean Berlin. Here the hospitals are not open to the general profession. One must have special permission to visit a hospital even once, and an outside physician cannot approach the bedside of a patient in a hospital unless he takes a course from a man connected with the institution. In Berlin, as in Paris, physicians connected with hospitals have usually only a few wards under them, and I am not aware of a single instance of a physician being connected with more than one hospital.

I do not think it is out of place to say that it would be a good thing for the medical profession in the United States if the same thing obtained here. A man like Dieulafoy in Paris, or Senator in Berlin, is connected with only one hospital, and yet they know something about medicine. The same is true with regard to the best European surgeons. It seems then that such a system is not detrimental to scientific medicine, but on the contrary seems to be favorable to it. Furthermore, some famous men in Europe are not connected with any medical college or hospital at all. Thus, Doyen, the Famous french surgeon, operates at his own private clinic. The same is done with respect to a number of famous men in Berlin. Some of the professors of the Berlin University are not connected with any hospital, but have their private polyclinics and clinics, and at the former they deliver lectures to students of the university. And this leads me to speak of post-graduate medical study in Berlin.

In Paris there are very few private polyclinics and none of the eminent medical men has any, whereas in Berlin the private polyclinic is as much in vogue as the dispensary is in New York. The hospitals in Berlin are few in comparison to those of Paris, and public dispensaries are also comparatively few; the polyclinic owned by one or two men, therefore, takes the place of the dispensary, and the private clinic supplies the needs of hospitals.

Some of the most eminent medical men in Germany have private polyclinics where they treat patients and give instructions to physicians, either in the shape of systematized courses or simply clinical demonstrations on patients as they come along. Usually both are given. In Paris, on the other hand, the eminent men have no private polyclinics, and the courses given to physicians are under the auspices of the university and take place during the vacation, though some courses are also given by non-university men, privately. In Berlin courses are being given in every field of medicine right along except during the summer vacations, when the best men are out of town. Of course the courses can be taken by any one who pays for them. Very few practical courses in Berlin are free. Only theoretical lectures are public. But practical instruction must be paid for. It is called in Germany "privatissime."

I shall now venture to say a few words concerning French and German medicine of the present day. To give a detailed description of the subject would require volumes and an abler pen than mine. I will refer merely to some fields of the vast science of medicine in which I took particular interest—namely, laboratory work as bearing upon medicine and gastointestinal diseases—and will at the same time make a few remarks about the methods of instruction in Paris and in Berlin.

In both cities instruction is given in laboratory technique, but it is in a different way. As I have said above, most of the courses in Paris are under the auspices of the university, and under the supervision of the respective professors of the university. I must say that for the general practitioner the courses given in Paris are more suitable and convenient than those of Berlin. The courses in laboratory technique usually consist of twenty to twenty-five lessons, two hours each, and they cover all the points that a general practitioner has to deal with. Thus the courses given in the several hospitals during the vacation time include uranalysis, examination of blood, elementary bacteriology, and in some cases also physical diagnosis.

A general practitioner who wishes to refresh his memory, and to see the new methods employed, can do so at a small expense and with little loss of time. This, of course, will not make of him a specialist in any of the subjects taught, but he can see what is being done in medicine, and he can gain enough elementary knowledge to help him in his daily practice.

This is not so in Berlin. One cannot get there a course covering many fields. Thus, one must go to one place for a course in uranalysis, to another for a course in examination of the blood, etc. Specialties exist in Germany to a greater extent than they do in France. "We do not make any specialties in France," is what the leading French physicians say.

In gastrointestinal diseases there is a difference in the methods of practice and instruction in the two cities. In Paris there are a number of very good men who take much interest in these diseases; but they do not make of it a specialty; but consider it as a part of internal medicine and are internists. Thus Hayem, Mathieu, and Robin, who have done so much work in gastrointestinal diseases, practise internal medicine. Not so in Germany. There some men are known as devoting themselves exclusively to gastrointestinal diseases, and they treat and teach nothing else.

The teaching in these diseases is done in Germany on a greater scale by far than in Paris. Clinics and courses are given in the latter city in these diseases in a desultory manner; but in Berlin there are men who instruct in these diseases right along, except when they are on their vacation.

Now, if we judge by the vast number of students from all over the world that flock to Berlin, we must say that so far Germany has the best of it, and the German methods seem to commend themselves better and to attract more students than the French methods. If France, one may unhesitatingly assert, was without a rival in medicine in the first half of the last century, within the last two decades Germany seems on the whole to be outrunning her. Germany's success in science seems to me to lie in the simplicity of the methods and in their practicability.

The notion is usually entertained that the German scientists are deep, whereas the French are light and superficial in their science. One has only to remember the legions of famous French scientists who have revolutionized the world to see the absurdity of such a notion. A scientist is deep and thorough, no matter to what nation he belongs; otherwise he is not a scientist. But there maybe a difference in the methods.

Let us take for illustration a new science in which

France and Germany have gained equal laurels, but in which I have no doubt Germany will soon outstrip France, unless the latter looks out for itself—namely, bacteriology. It is hard to say who has done more for this science, Pasteur or Koch, and it is equally hard to say where more is being done for it now, in France or in Germany. One has only to remember the great work done in the famous Pasteur Institute in Paris to know that France is doing a great deal in it. Yet the German methods will commend themselves sooner than the French ones. First, the laboratory outfit. One can fit up a laboratory according to Koch's methods, which are prevailing in Germany, at a comparatively little cost. The apparatus used in the Hygienische Institut, 34 Kloster Street, Berlin, where Koch and his followers have made the most glorious discoveries, are simple and inexpensive. A simple *dampftopf* or steam sterilizer takes the place of the costly autoclave used in all the laboratories of Paris. There is no question that the autoclave is more scientific than the dampftopf; but since one can do as good work with a simple inexpensive instrument, why employ complicated machinery? The same concerning Koch's dry heat sterilizer and the *four Pasteur*, the former used in Berlin, the latter in Paris.

Another point. In Paris, in the Institut Pasteur especially, they plume themselves on the fact that they know how to make by themselves glass pipettes, and other little things for laboratory use, whereas in Germany, up to very recently, it had not been done. The reason for it is that the German bacteriologist does not need it. When a French bacteriologist wishes to get a certain amount of a virulent culture in bouillon, or another fluid medium, he aspirates it with a pipette. Not to speak of the danger, it is certainly most unpleasant to aspirate virulent cultures with the mouth through a pipette, as the French usually do, and as the French textbooks usually teach. The German uses for this the loop of a platinum wire needle. He takes so many loops or *Osen* instead of taking so many drops from a pipette, as the Frenchman does. The German uses a pipette only for innocuous fluids like water, milk, etc., so he can buy a pipette ready made, and it will last him a long time. But there is no question that so many drops from a filiform pipette are more determined in quality than so many drops from a loop of a platinum wire needle. But the latter method is simpler, safer, and is practically as good.

Let us glance at gastrointestinal diseases. In all the hospitals of Paris where these diseases are specially treated the method of Hayem and Winter for determining the hydrochloric acid in the gastric contents is employed. This method, as everyone who is familiar with this subject knows, is rather complicated, requires a great deal of time, and is not of easy application. I will say nothing of the merits of this method, but will only remark that in Paris they think that this is the only method for determining the hydrochloric acid in the gastric contents, and they teach it and practise it; whereas in Berlin they think it is too complicated, unpractical, and valueless, and not a single eminent gastrointestinal specialist uses it. The German method is certainly more easy of application than the French one.

I could multiply examples, but from the above it will be seen that the French methods are not superficial, but rather too complicated, whereas, on the contrary, the German methods are simple, practical, and of easy application, and that is why they commend themselves better to the world. And there is no doubt that better results can be obtained with simple than with complicated methods.

321 EAST THIRTEENTH STREET, NEW YORK.

A SUGGESTION FOR INCREASING THE VALUE OF THE CYSTOSCOPE IN CASES OF HÆMATURIA.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR: Since the introduction of cystoscopy some years ago, specialists have often deplored the ineffectiveness of the cystoscope in those cases when severe hemorrhage from some portion of the upper genitourinary tract renders ocular inspection of the bladder difficult and unsatisfactory. It is true that Nitze, Casper, and others have endeavored to correct this shortcoming by suitable attachments to their respective instruments, whereby it is possible to have a stream of water play constantly over the little prism at the distal end of the cystoscope, and thus, in a measure, keep the lens clear of clotted blood. Notwithstanding these ingenious arrangements, the continual escape of blood into the bladder rapidly discolors the fluid contained therein, and thus obscures the field of vision. Several cases of hæmaturia recently under my care, and in which cystoscopy proved of little value, prompted me to seek for some means whereby cystoscopy under such circumstances could be made just as effective as it is in more favorable instances. Different solutions were injected into the blood-discolored uterus, with the hope that in this way the dark red color would be rendered transparent. These experiments proved negative. Experiments on the line of neutralizing the red color by means of different colored lenses were then made. Glasses of different hues were interposed between the eye and the ocular end of the cystoscope. While in one instance the colored fluid was rendered lighter, the density of the color was not changed. It was then thought to replace the ordinary prism with one of a certain color, but this too failed to secure the desired object.

Believing that failures often lead to success, I may be pardoned for suggesting this line of experimentation, in the hope that it may prove successful in other hands. The idea is so obvious that it may possibly have occurred to some one before me, in which case I shall cheerfully yield priority. Some chemist or physicist may possibly suggest some plea whereby the problem can be solved.

Progress of Medical Science.

The Boston Medical and Surgical Journal, July 21, 1904.

A Method for Obtaining Sputa for Bacteriological Examination in Infants and Young Children.—C. W. Townsend declares that the diagnosis of many cases is often difficult in children under five or six years of age, because although they cough up sputa into the mouth, they swallow instead of spitting it out. Especially is this true of cases of delayed resolution in bronchopneumonia, many of these having an evening rise of temperature, so that the tuberculin test cannot be used. Holt has recommended the passage of a stomach tube, and the examination of the mucus that adheres to it. The writer has found a metho which has recently been described by Findlay, and used for some time in the French hospitals, very simple and very satisfactory. It consists in sweeping the finger covered with gauze over the glottis and epiglottis. This causes reflex coughing, and the expelled mucus is caught in the meshes of the gauze.

Interstitial Colitis, Simulating Cancer of the Rectum.—J. W. Elliott in describing this case notes that the patient had had constipation and dyspepsia for the last twelve years, but for the last few months she had had a subacute difficulty, constipation and diarrhœa alternating. She came for advice for what she thought was a tumor of the rectum. There was a hard mass there that felt like a cancer. Pus and blood were coming constantly, and the writer had no doubt that it was cancer. He intended to resect the rectum and part of the sigmoid flexure, but when the abdomen was opened up, the whole gut, from the anus up to the splenic flexure, was one solid tube of large caliber, and so fixed that it could hardly be moved. Resecting was out of the question, so he simply made an artificial anus on the other side. The mass had such a strange appearance that the writer doubted if it could be cancer. It was scraped and examined, and the report came back negative—simple inflammatory tissue. The whole descending colon down to the rectum was chronically inflamed—interstitial colitis. The patient is now very much better. There has been no sloughing, and the pain is all gone. The writer believes that this is the proper treatment for such a condition—sidetrack the fæces and wash through.

Journal of the American Medical Association, July 23, 1904.

Period of Incubation of Tetanus.—Albert Woldert reports a case in which an amputation was performed about the lower third of the thigh for gangrene following a lacerated and contused wound about four inches below the knee-joint, with fracture of the leg at this point. One week after the injury marked symptoms of tetanus appeared.

Acrodermatitis Controlled by the X-ray.—Douglas W. Montgomery says that cases constituting the group "the continued acrodermatitides" are characterized by their location on the extremities of the members, more particularly in the fingers and toes, by their incessant recurrence in the affected locality, by their not extending for a long time to any other region of the body, and by their obstinate resistance to treatment. Three forms of this malady are described—a vesicular form, a pustular form, and a form in which there are both vesicles and pustules. The case reported falls under the vesicular group, and the patient received nine exposures with the most satisfactory results, the attack being quickly subsided.

The Character of Chromatophores.—Leo Loeb says that different views are still held regarding the origin of the cell masses characteristic of pigmented moles and in regard to the origin of the melanotic tumors of the skin, a

number of pathologists believing in the epithelial origin of nævi and of melanotic tumors, others assuming a mesodermal origin. Loeb says the pigment originates in the epidermis, and the production of malanin is a peculiarity of certain epithelial cells which preserve this function if they are transplanted to a place where formerly non-pigmented cells were present. The melanin in the chromatophores is probably derived from the proteid substances of the cell, and is very likely not directly produced from a derivative of the hæmoglobin for the following reasons: (1) The sulphur content of the melanin is very large. (2) From the melanin decomposition products can be obtained similar to the ones obtained from the melanoidins, which themselves can be produced with the aid of acids from proteid substances. (3) Tyrosin, a radical, present in cell proteids, can, with the aid of an oxidative ferment tyrosinase, be transformed into substances similar to the melanin of sepia, and similar, probably, to the melanins of vertebrates. It is, therefore, not unlikely that the production of the pigment of the chromatophores is due to a fermentation causing oxidative and condensation processes in certain decomposition products of cell proteids.

Medical News, July 23, 1904.

Personal Experience in the Treatment of Typhoid Fever.—Carter S. Cole, from his large experience in the treatment of this disease, concludes that: Fever is a necessary part of the disease, and varies according to the week in which it occurs. We cannot change the type, although we may control the fever. The use of coal-tar products for the reduction of temperature is seldom if ever desirable, but the use of water externally and internally is a necessary part of the treatment of the disease. Nutrition must be liquid, and must be adapted to the individual case. Lastly, medication plays a very small part in the management of the disease, and is only used to meet special indications.

A New Brace for the Shoulder-joint.—Leonard W. Ely describes a simple brace which can be made by any brace-maker. It consists of a belt of canvas three or four inches wide, which encircles the chest just below the axillæ, and laces in front. A similar belt encircles the arm. These two belts are joined by two flat, arching metal rods, in front and behind, on whose inner ends are riveted metal plates to prevent twisting of the thorax girdle. Finally the thorax band is provided with a pair of suspenders to prevent sagging. The writer devised this apparatus for a case of tuberculous shoulder-joint disease. It permits motion and use of the forearm, and restricts motion of the shoulder in every direction, except rotation—the least harmful of all motions of the joint.

A Visit to Gheel.—Smith Ely Jelliffe describes in a most interesting manner his visit to this picturesque retreat. The colony consists of a poor rural community, small farms, occupied by low one-story dwellings, tiny villages with the town of Gheel at their center, and meadow lands traversed now by tram cars, much like the American trolley. The colony is a retreat for the insane, but no patients are admitted to it who must be continually kept under restraint, nor who could offend public decency, and none who have homicidal, suicidal, or incendiary tendencies. All who are able to work are paid a small sum each week by their nurses or hosts. The work varies according to the patient. According to their value as workers, or to the care they require as patients, the sum paid to their nurses, for their board by the State, varies. Paupers who are able to work and who are quiet and orderly belong to the first class. In this class are a good many idiots and dements. Those who are noisy or semi-depraved are placed in the second class. Patients of the third class, wholly depraved or epileptic, bring the largest revenue to their nurses. Patients whose friends have means can be lodged at a still higher rate in the homes of the well-to-do. For, through the long establishment of the custom, the permission to have patients is largely sought as a favor by nearly all the householders of Gheel. From a medical point of view, the colony is divided into four sections, each of which is cared for by a physician, who has two section guards to help him. These physicians must devote themselves exclusively to the care of the insane, and are formally forbidden to practise, except in matters of expert medicolegal work. Four men and eight deputies attend systematically to over 2,000 patients, and no paid attendants are employed. The system is arranged far more economically than our own institutions. The personal interest and oversight of the medical director was apparent at once. The bare walls were spotless, as were the windows and plain furniture and bedding. Thrift and good management were everywhere in evidence. In the tours of inspection the physician goes into the patient's bedroom, rips open the bed, looks at the sheets and blankets, and examines the garments hanging on the wall. The report is entered on a card. The guardians are obliged to feed their patients as well as their payments will permit, as a sort of check is kept upon them by means of the bathhouse weighing system. The writer concludes by saying that if in this country we could find here and there a simple kindly farming community discouraged by the stern laws of supply and demand, and imbue the inhabitants with a combined spirit of philanthropy and commercialism, we might gradually with great tact find homes for many thousands of our insane, in the course of the next fifty years.

New York Medical Journal, July 23, 1904.

The Radiant Light Bath in the Treatment of Neuroses.—T. D. Crothers summarizes his conclusions as follows: (1) The radiant light penetrating to the deeper tissues of the body is turned into heat or transformed into nerve energy more positively than is heat from hot air. (2) The clinical effects of the bath prove its power as an eliminating agent and a corrector of neurotic, nutrient, and capillary disturbance. (3) In neurotic diseases its action in conjunction with other measures is far superior to any of these means when used alone. (4) The evidence so far points unmistakably to the possibilities that when used in connection with other electrotherapeutic measures it may come into general use and constitute a real advance in the progress of neurological therapeutics.

The Treatment of Crushing Injuries Involving one Articular Surface of an Interphalangeal Joint.—John H. Sheldon advises the following method of treatment: Thorough mechanical cleansing with sterile water; resection of the destroyed articular end of the phalanx, followed by shaping the end of the bone to fit the apposed articular surface; closure of the new-formed joint by the suturing of ligaments, tendons, and fascia with catgut; application of splints and a moist aseptic dressing. The reasons for advising this method and the objects to be oblained were these: (1) In most of the cases the skin and subcutaneous tissues are so injured and infiltrated with foreign material that complete disinfection is impossible. (2) The bones and deeper structures are usually not so badly injured as are the soft parts, and they can be rendered practically sterile. (3) If the deep structures are clean and the upper ones likely to suppurate, a barrier should be placed between them. This method of treatment prevents extensive suppuration in the skin from affecting the bones, provided efficient primary drainage is secured, which is done by not suturing the skin, and by the application of a moist dressing. Five cases are reported.

A Unique Case of Chorea.—James T. Wrightson records the following case: The patient was a woman, twenty-one years old, who, when six years old, had a very slight attack of chorea, which was controlled by small doses of arsenic. She was married in June, 1903, and in August did not menstruate. In September there were irregular facial contractions, which gradually increased in severity and distribution, involving finally the muscles of the extremities and those of phonation and deglutition. There was absolutely no sleep or rest; her tongue was bitten and thickened almost occluding her mouth. Nourishment was much impaired. Muscular activity was so violent as to endanger her life and she had to be bandaged like a papoose. This clinical picture lasted from September 20 to October 20. Arsenic, bromides, morphine, etc., were given, but it was not until sodium salicylate was resorted to in large and repeated doses, fifteen grains every three hours, that any decided change was noticed. At the end of two weeks she was able to carry food to her mouth. Then her left pleural cavity began to fill, and within one week there was an exudate of three pints, which was evacuated. An uneventful recovery then occurred. Her pregnancy has continued, and is now at the fifth month.

American Medicine, July 23, 1904.

Loss of One-quarter of Brain Substance with Consciousness and Ability to Talk Retained until Death.—Henry S. Wieder reports the case of a white man, thirty years of age, who fell twenty feet, landing upon his head. There was an H-shaped fracture of the vault of the skull, going down into the base, nose, and right eye, and brain tissue was scattered all over his scalp. As the opening into the cranial cavity was so large, and there was no possibility of pressure upon the brain beneath, no operation was necessary. The wound was dressed and the nose tightly packed with gauze, but still there was free bleeding from nose and mouth. Later the pulse became weak, the temperature rose, and death occurred the same day. But the patient remained conscious and talked till about an hour before death. The writer sums up the interesting points: In spite of the severity of the injury, the height of the fall, and the evident injury to a large portion of brain-tissue, the patient did not lose consciousness. He retained his mental faculties and reasoning powers, although a

large portion of the cortex of the right hemisphere of the brain quite far forward and including the frontal lobe was removed, in addition to a considerable quantity lost at the time of the accident. This was proved by the fact that he at first refused to give his address, but later did so, on being told the seriousness of his injury, and that he answered questions until very shortly before he died. The localization of the speech center is well shown to have been on the left side of his brain, as demonstrated by the fact that his speech was not impaired beyond the physical disability due to paralysis of the facial muscles. The evident absence of pain or sensation in the cerebral matter, although a well-known fact, was very forcibly illustrated in this case, for rarely in the human being does the surgeon have an opportunity to find a subject conscious while he is removing brain tissue.

Metabolic Changes Caused by External Hemorrhage.—William J. Gies carried out his experiments on dogs. The food consisted of prepared hashed meat, cracker meal, lard, bone ash, and water. This mixture was given daily in uniform quantities of constant composition, and at regular intervals. Each dog was brought into nitrogenous equilibrium at the beginning of each experiment, and after remaining in this condition a week or more, was subjected to repeated hemorrhages at intervals of one to three weeks. The quantities of blood withdrawn were usually 3 per cent. to 3.5 per cent. of body-weight. The writer draws certain general conclusions from many concordant results: In well-nourished animals, in weight and nitrogen equilibrium, and fed continuously on a diet of constant composition, there was a temporarily increased output of nitrogenous and sulphur-containing products in the urine, and a variable effect on the elimination of phosphorized substances, although mainly a decreased excretion of the latter. Proteid catabolism was somewhat stimulated therefore. Total solids in the urine were increased with the nitrogen and sulphur catabolism. These effects were relatively slight after one bleeding of moderate amount, but became more marked and lasted longer with repeated losses of blood. The increased elimination of the catabolic products above mentioned occurred only in the urine. The amount, consistence, and composition of the fæces were apparently unaffected by the hemorrhage. Digestion did not appear to be materially disturbed at any time, even after several severe hemorrhages at short intervals. There was little or no effect on intestinal putrefaction. Body-weight steadily declined after each bleeding. When the animal was allowed to eat freely, however, hemorrhages were followed by gradually increased weight. Moderate loss of blood markedly increased the appetite and caused thirst, even when the animal was receiving an excess of food. Excessive losses of blood had temporarily an opposite effect. Hemorrhage caused an immediate stoppage of the formation of urine, and subsequent retardation of flow, lasting a few hours, and finally a decided stimulation. On returning the blood (defibrinated), urine immediately began to form, and flowed under specially stimulating influences. Hemorrhage inhibited the hypersecretion of saliva during the periods of ether anæsthesia connected with the surgical procedures. The urine was always decidedly acid in reaction before hemorrhage; slightly amphoteric occasionally. After hemorrhage, it was strongly amphoteric for several days. The only abnormality noted in the urine was a transient glycosuria, apparently due to the anæsthetic. After successive hemorrhages, the percentage of proteid and nitrogenous products in the blood gradually fell; that of phosphorized and sulphur-containing substances, and the ash, remained practically stationary. Specific gravity fell and water content rose in each successive sample of blood, even when they were taken at wide intervals. Each of the metabolism experiments gave results indicating a relatively slight and only temporary increase in nitrogenous elimination after hemorrhage. Loss of blood, if considerable, at once affects the higher nerve centers by diminishing the supply of material available for their nutrition. Such changes disturb various important chemical and physical functions. The blood-making organs are stimulated to exceptional activity. Sugar and other substances are present in the blood above the normal proportions for a while. It is not improbable that during the first few hours after a hemorrhage there may be subnormal metabolism, followed by a greatly stimulated metabolism.

Lancet, July 16, 1904.

Vincent's Angina.—H. W. Bruce says that this is a form of pseudodiphtheria which is associated with, and is probably due to, certain characteristic microorganisms. The form of pseudodiphtheria illustrated by the ten cases on which the paper is based was first described by Vincent in 1898. The disease is not infrequent, but its frequency is masked by the fact that it is often confounded with diphtheria. The pathological processes in the two diseases are quite different; when a considerable amount of destruction of tissue has taken place in Vincent's angina, the distinction is made readily enough. But when the necrosis is quite superficial, the resemblance to diphtheria is very close. A positive diagnosis then is only possible by bacteriological examination. The bacillus which Vincent has called the "fusiform bacillus" is very long. Its center is a little thickened and its ends somewhat pointed. They are usually distributed uniformly through the field although they may be present in such numbers as to form almost solid masses. Shorter forms are sometimes seen occasionally curved and comma-shaped. It does not yield the Neisser staining reaction, and it is decolorized by the Gram method. Its motility is doubtful. So far all attempts to cultivate it have failed. With this bacillus is frequently found associated a spirillum which is only faintly stained by the ordinary reagents, decolorized by the Gram method, is motile and, like the bacillus, has never been cultivated. At the commencement of the disease either the bacillus or the bacillus and spirillum are found almost pure in the pseudomembrane, but later they become mixed with numerous other microorganism which inhabit the mouth.

Diet in Chronic Heart Disease.—Theodore Schott says the principal and fundamental rules may be conveniently summed up in the two clauses: (1) patients must avoid everything which excites the action of the heart; and (2) everything must be avoided which embarrasses the action of the heart. Under (1) he places strong coffee or strong tea and strong alcoholic liquors. The best beverages are by far ordinary water or milk; next in order comes tea or coffee, both with copious additions of milk. If patients need fatty material, cream should be given either plain or added to milk. Cocoa deprived of its fat is strongly recommended. With regard to the second rule given, patients should avoid that which would cause any considerable gastric distension and should eat nothing which is difficult of digestion or tends to produce flatulency. Too hearty eating or the ingestion of substances which produce flatulence may be harmful in three ways: (1) The diaphragm is pressed up against the lungs so that respiration is impeded and there is shortness of breath and dyspnœa. (2) The distended stomach also presses the diaphragm directly against the heart, displacing it in the direction of its base in such a way that its action can only be carried on with a greatly increased effort. (3) In like manner the intraabdominal pressure is augmented and the abdominal vessels are compressed. For this reason effervescing beverages disagree with these patients. They should never eat until there is a feeling of repletion; small amounts of food should be taken at shorter intervals than three times a day. It is impossible to urge too strongly that sufferers from heart disease always require a mixed diet. His experience led him to regard tobacco with especial disfavor. Exercise after eating is to be recommended, but it is quite essential that the individual characteristics of the patients should be studied and the treatment modified in correspondence with the symptoms.

Note on the Value of Kader's Operation of Gastrostomy.—J. Crawford Renton recently performed this operation four times and wished to record his satisfaction with it, both as regards rapidity and ease in carrying out the details and its efficiency as a means of feeding the patient and insuring no escape of fluid from the stomach, even when coughing. The usual incision for gastrostomy is made when four retaining loops of silk are passed through the peritoneum and placed equidistantly round the opening, pressure forceps being applied to each. This prevents the peritoneum sinking down when the stomach is withdrawn. Three inches of stomach, as near the cardiac end as possible, are drawn out; the peritoneum and aponeurosis are carefully stitched to the stomach, using a Reverdin's curved needle; the stomach is then opened and a No. 12 soft catheter is introduced and fixed in position by a fine suture which passes through the whole thickness of the stomach wall and is tied tightly round the catheter. The stomach is now invaginated by pressing upon the firmly secured tube and a purse-string suture is introduced a quarter of an inch below the opening into the stomach. This is drawn up and tightened round the tube; a second purse-string suture is introduced half an inch below the first, the stomach being further invaginated and the stitches tightened around the tube; a third purse-string is introduced half an inch below the second if necessary and tied round the tube. In this way a valve is formed inside the stomach so that the tube can be easily passed in, and when removed the valve comes together and completely closes the opening. The skin incision is united with silkworm gut. After the wound is healed the patient soon learns to feed himself. Having first chewed the food he passes it into the tube which is inserted into the stomach.

British Medical Journal, July 9, 1904.

Air in the Heart.—P. O. Malabre reports the case of a woman aged sixty who was found dead in an open field. There was no external sign of violence. The pericardium was bulging, especially over the right ventricle. The right side of the heart was distended with air or gas which hissed out when an incision was made, leaving nothing but dark frothy blood in the right cavities. In the left ventricle was only a small post-mortem clot. Nothing abnormal was seen in the air passages or large vessels at the root of the neck. The writer thinks that the air was the cause of death, but found it impossible to trace the source of the air.

Traumatism and Hernia.—William Sheen concludes that, granting the existence of a preformed sac, oblique inguinal hernia may occur suddenly as the result of a single trauma, such trauma being usually an abdominal "strain." It is doubtful whether the preformed sac is congenital or acquired. For the trauma to be the cause of the hernia, certain conditions must be fulfilled. These conditions are tabulated as follows: The trauma must be of a certain character, either a sudden general muscular contraction compressing the abdominal contents, as in lifting too heavy a weight or in resisting a blow, or possibly a general abdominal squeezing, as in a buffer injury. A localized blow on one part of the abdomen (as by the end of a stick) cannot cause a hernia. The hernia must be quite small at first. The hernia must appear immediately after the accident. The development of the hernia must be accompanied by acute pain and tenderness at the site of the hernia and by the formation of a small, tender lump there. The symptoms must be so acute as to compel the patient at once to leave his work and seek medical aid. A few more points are mentioned by the writer. If the case is one of hernia into the tunica vaginalis, the hernia may reach the scrotum as the immediate result of the traumatism. The existence of a double hernia is against traumatism. Operation may at times afford additional information of medicolegal value. When a hernia exists previous to the trauma, the trauma may determine such a change in the hernia as to unfit the man for his work. It must be recognized that the association of hernia with trauma is exceptional. No exact rules can be laid down, and every case must be judged separately.

The Surgical Anatomy of the Normal and Enlarged Prostate—and the Operation of Suprapubic Prostatectomy.—J. W. Thomson Walker presents this paper. He first describes the normal prostate. The pelvic fascia provides a complete sheath for the prostate, which envelops it except at its basal attachment to the bladder and at its extreme apex. The base of the prostate lies beneath the bladder base. The outer longitudinal layer of bladder muscle is attached to the posterior border of the prostatic base and many fibers become incorporated with the true capsule of the gland. A circular layer of striped muscle completely surrounds the apex of the prostate for about a quarter of an inch. The muscle is continuous below with the constrictor urethræ. The veins of the prostatic plexus course upward in the anterior layer of the sheath on the base of the prostate and then backward around the junction of the prostate and bladder, forming a Y with a vertical stem and horizontal arms. The capsule of the prostate corresponds to the capsule of other glands. Two bands of prostatic tissue unite the lateral lobes behind the urethra, one above the ejaculatory ducts and the other below them. The connection between the prostate and the urethra at the level of the verumontanum and above this eminence is intimate because of the presence of the prostatic ducts, but below this level the two structures merely come into relation with one another. The seminal vesicles lie along the upper border of the posterior aspect of the prostate and take a transverse direction, not a vertical one as is described. Some of the changes in the enlarged organ are as follows: The sheath of the enlarged prostate is a densely woven envelope of considerable thickness. Another striking change takes place in the relations of the enlarging prostate and its sheath. The upper part of the posterior surface already lies in a corner between the bladder. muscle and the lower border of the seminal vesiclsr. As the enlargement proceeds, this wedge insinutaes itself between the bladder wall and the vesicles so that these structures become more and more separated. Finally the vesicles are pushed back till they lie behind the upper part of the gland instead of above it. Often nodules of the enlarged prostate intrude themselves within the bladder cavity and are only covered by bladder mucous membrane. The middle lobe of the prostate is formed by the protusion of a nodule between the two bands of muscle which pass into the trigone from the uret rs and unite on the posterior wall of the prostatic urethra. The urethral mucous membrane is dragged up into the bladder, which probably explains the frequency of micturition. The writer then gives some observations on the operation of prostatectomy, and remarks that it is not to be supposed that in every case the operation is faultless. In a few cases a shred of prostatic tissue is left behind. But small bits of prostate left behind are accidents of the operation, and not proofs of its incompleteness.

Deutsche medizinische Wochenschrift, June 30, 1904.

The Production of Specific Substances from Typhoid Bacilli.—L. Brieger and M. Meyer submit the following conclusions based on the results of their practical experiments: If living typhoid bacilli, twenty-four hours old, are suspended in sterile water for six to twenty-four hours, those substances which are able to generate specific agglutinins and bacteriolysins, are found to have been transmitted in great part to the fluid and are also present in the filtrate which is free from the germs themselves. The amount is greatly increased when the mixture is thoroughly shaken for a considerable period. The authors believe that filtrates of this character are particularly applicable for the purposes of active immunization, as no toxic action has been observed to follow their injection. On the other hand, filtrates secured by autolysis in the incubator were found to be markedly toxic for rabbits, on account of the large amount of bacterial substance held in solution.

A Specific Precipitin Reaction with Bothriocephalus Latus.—Isaac and von den Velden believe from their observations in a case in which the parasite was present, that the blood serum of the patient contains a specific precipitin for this tape-worm. This means that in all probability albuminoid bodies derived from the tænia entered the circulation and induced the production of a precipitin. The question remains as to the origin of these albuminoids: were they formed as the result of an autolysis of certain of the proglottidæ, or should they be considered as products of the living parasite? Absorption probably occurred through the intestinal mucous membrane, but as this is not possible under normal conditions, it must be assumed that some anatomical or functional injury took place which was brought about by some metabolic process or the suction disks of the animal.

Prognosis and Treatment of Puerperal Pyæmia.—E. Opitz presents an extensive review of this subject. He believes that operative treatment for this condition, as recommended by Trendelenburg, will only be followed by good results in exceptional cases, but it is almost impossible to state these indications in a definite manner. Trendelenburg's procedure consists of the ligation or removal of the diseased veins, with or without total extirpation of the uterus. Opitz claims that the main factor in the treatment consists of prophylaxis. Where a pyæmia is already present better results will be obtained from a course of treatment which includes absolute rest in bed, proper and sufficient nourishment, supplemented by infusions or rectal injections of saline or sugar solutions, than from alcohol medication. A certain amount of good also follows the administration of nuclein, antipyrin, and the intravenous injection of collargol.

Deutsche medizinische Wochenschrift, July 7, 1904.

Simultaneous Primary Tuberculous Infection through Intestine and Lungs.—Ribbert has met with three cases in which there was a double primary infection, and claims that this may readily happen, because when an individual inhales the tubercle bacilli, a certain number adhere to the oral mucous membrane and are later unavoidably swallowed. These cases also show conclusively the production of primary intestinal tuberculosis by the agency of the human bacillus. It seems scarcely logical to assume that the infection of the gut was due to bacilli from cattle, while that of the lungs was brought about by infection with the human bacillus. Such a double infection also gives rise to the thought that inspired bacilli may be swallowed in great number and that only in such cases is the intestine primarily infected. It is also worthy of note, as already suggested by v. Behring, that milk and other infant foods may be contaminated by bacilli of human origin, and that primary intestinal infection may result in this wise. All these suppositions point to the fact that in primary intestinal tuberculosis an infection with the human bacillus should be thought of, rather than with the bacillus from cattle, as was formerly the more prevalent idea.

Technique of Ficker's Method of Typhoid Diagnosis.—Clamann suggests a modification of certain details in this method. In place of the scarifying instrument, he advises the abstraction of the blood directly from a vein in the arm by means of a hypodermic syringe without a needle. The syringe should be of a pattern which permits sterilization by boiling. After the syringe is filled with about one c.c. of blood as it flows from the wound, the opening may be closed with sterile wax or a small rubber cap, and

the instrument transported to the laboratory. When ready to make the test, the syringe is placed over the test-tube containing the diagnostic serum and the piston slightly withdrawn. This liberates the clot at the opening and the serum contained in the barrel finds its way out.

Pulmonary Infusions for the Diagnosis and Treatment of Tuberculosis.—P. Jacob, Bongert, and A. Rosenberg present the results of an extensive study, both experimental and clinical, in this field of research. The technique of the method in man is as follows: Under the guidance of a throat mirror, the laryngeal surface of the epiglottis and the vocal cords are anæsthetized with a few drops of a 20 per cent. cocaine solution. Shortly after, a thin rubber tracheal spray is introduced through the glottis, and through it the trachea is sprayed with several c.c. of a 2½ per cent. b-cocaine solution. This may induce coughing, but this soon ceases. A bougie is then introduced into the trachea, provided with a very flexible stilet. After the latter is removed, the bougie may be carefully pushed down into either the right of the left main bronchus. The tuberculin is then slowly injected through the bougie by means of a syringe. The quantity of fluid was usually about 20 to 30 c.c. of 0.01 to 0.02 of the tuberculin, to 100 of water. The amount of tuberculin is increased as the reaction disappears. After the injection, the patients are put in the horizontal position, as in this way the solution finds its way into the upper sections of the lung, as shown in the animal experiments. The procedure is claimed by the authors to occupy not more than ten minutes and is well borne by the patient after a few sessions. The method was applied in five cases of pulmonary tuberculosis, all of which were in the second stage of the disease and in a poorly nourished condition. The infusions were given in varying numbers: in one thirty-eight were given in four and a half months; another, eighteen in two and a half months The results in all were excellent and the patients were dismissed as clinically cured, being relieved of their symptoms, free from physical signs, and having gained in weight. No unpleasant consequences were noted, and the method seemed to be harmless. The authors believe that the adoption of this method will not only prove of value as a therapeutic procedure, but also furnish a diagnostic aid. For it was found that if an individual is afflicted with pulmonary tuberculosis, the infusion of tuberculin, as here described, will be followed by a reaction, if only one-tenth or one-twelfth of the dose is given which is necessary to obtain a reaction by the method of subcutaneous injection. If the tuberculous processis localized in some other part of the body than the lungs, the reaction after the infusion will only appear after an equal or a larger dose has been injected than would be required for the subcutaneous injection. A more detailed report of these interesting investigations will be published in a special monograph.

Berliner klinische Wochenschrift, July 4, 1904.

Borax in the Treatment of Epilepsy.—J. Hoppe reports on twelve cases of epilepsy in which this drug was given in doses of from 1 to 3 grams daily. The patients all manifested a marked intolerance of the bromides. In seven of these cases the administration was unattended by any results whatever, and in some symptoms of intoxication became evident. Most of the patients presented some defects in their excretory organs, and the drug seems therefore to be contraindicated in such cases. Improvement was noted in five patients, both in the lessened number of attacks and the general health. In a number of recent cases borax was given for a period of six weeks, but the effect was not as good as that following the use of the bromides.

Tuberculosis of the Larynx and Interruption of Pregnancy.—R. Sokolowsky comments on the advisability of interrupting pregnancy where a well-developed tuberculous laryngitis is present, and reports two cases in which even this procedure was insufficient to prevent the extension of the disease and the death of both patients. In one, labor was induced during the eighth, in the other during the sixth month. The operative procedure was well borne and the subjective symptoms were improved for a short time, but death came on in both within a month after delivery. Two similar cases were also reported by Golkesen, and the author claims that these four cases show the necessity for doing an abortion as early as possible, rather than wait, as in this instance, until the later months. Moreover, every woman who is afflicted with tuberculosis of the larynx should be warned against the dangers of becoming pregnant.

Munchener medizinische Wochenschrift, July 5, 1904.

Blood-plates and the Coagulation of the Blood.—K. Bürker submits the results of his experiments undertaken with the idea of determining the rôle these structures play in producing coagulation of the blood. The difficulty attending the isolation of these delicate structures was overcome by a special method devised by the author, which must be studied in the original. The author found that there is a direct relation between the amount of fibrin formed and the number of disintegrated blood-plates, for microscopic preparations showed that where only a few blood-plates were present, the number of fibrin shreds after coagulation were also reduced in number, and *vice versa*. The disintegration of the blood-plates keeps pace with the coagulation when under the influence of varying temperatures. Thus, they may be preserved intact for several hours or days, at a temperature a few degrees above zero (C.), whereas they rapidly break up at the temperature of the body. In a similar manner, coagulation is delayed by cold and accelerated by heat. The author concludes with the statement that coagulation in blood recently taken from the body is closely connected with the typical disintegration of the blood-plates.

Erythrocytosis and Splenomegaly.—Zaudy reported a unique case some time ago in which these two conditions were associated and upon which he now publishes further comments. The patient, a woman of twenty-seven, complained of gastric symptoms, which were at first attributed to gastric ulcer. Examination disclosed a very much enlarged spleen, which was stated to have been present for eight years. Examination showed the blood to be somewhat more dense than ordinarily, the erythrocytes numbered 9,400,000, and the white cells were about in the proportion of 1:570. Otherwise the patient seemed to be in good health and refused to remain under observation. The author now attempts to explain the case by assuming that the gastric fever complained of eight years previously was a mild case of typhoid fever, and that the enlarged spleen failed to recede. Owing to this enlarged organ, or to a perisplenitis, compression of the splenic vein resulted or it became displaced in such a way that congestion of the spleen resulted. This interfered with the normal destruction of the red cells, and resulted in an increased number of the latter in the blood. This is offered as a probable explanation, but is not advanced by the author as infallible. It remains to await the report of similar cases.

Non-operative Treatment of Aural Inflammations.—R. Panse decries the methods employed by the laity in treating ear affections, and claims that they have as little moral right to treat the aural cavity as they have any other wound. Especial harm is done by the dropping of hot oil into the canal and irrigations with various fluids. The oil forms a paste with the ear wax which is most difficult of removal, contains many germs and obstructs free drainage. Irrigations with the ordinary glass syringe are also ineffective, because the fluid rarely reaches the diseased area. The effects of localized heat are much more readily secured by warm external applications. Where it is determined to apply drops, the best form consists of a solution of carbolic acid (less than 5 per cent.) in glycerin, which is hydroscopic. Irrigations also fail to remove any pus from the middle ear, as will be readily seen from the anatomical conformation of the parts, unless a catheter is employed. The author has restricted himself, in using irrigations, to impacted ear wax and foreign bodies. Paracentesis is urged in all cases in which there is a bulging drum membrane, and after cleaning out the canal, a small quantity of iodoform and boric acid powder should be insufflated, and a light gauze packing introduced. In order to avoid softening of the epidermis and consequent secondary infection, it is well to brush the external canal every few days with a ½-per cent. solution of nitrate of silver. The careful applications of the methods outlined will, in the author's opinion, save many cases which would otherwise need operation.

French and Italian Journals.

Orbital Thrombophlebitis Following Furunculosis of the Nose.—Cabanes describes this case. The patient had three boils on the nose. Quickly double exophthalmos developed, with chemosis and inflammatory swelling of the upper eyelids. At the end of forty-eight hours after his entrance to the hospital, the patient died in coma. Autopsy showed an obliterating phlebitis of the right ophthalmic vein of the two cavernous sinuses and of the right sylvian region. The clots in the cavernous sinus and ophthalmic vein were beginning to suppurate. The pus contained the yellow staphylococcus in pure culture.—*La Médecine Moderne*, June 29, 1904.

Appendicitis or Intestinal Occlusion by Invagination.—Delassus concludes that the differential diagnosis between appendicitis and occlusion by intestinal invagination is sometimes very difficult, and in such cases operation should be performed. The symptoms of intestinal occlusion are not always clear, and those which indicate peritoneal reaction may completely mask those to which occlusion gives rise—hence the confusion. It would seem that the ascending form of invagination in causing a more complete suppression of the passage of gas and

fecal matter causes a more rapid development of this affection.—*Journal des Sciences Médicales de Lille*, June 25, 1904.

Negri's Bodies in Etiological Relation to Rabies.—Luigi d'Amato has examined forty-eight cases of rabies in animals, and five control animals that were normal, with reference to the presence of the endocellular corpuscle described by Negri as being present in the tissues of the nervous system, especially in the cornu ammonis. His conclusions are as follows: The corpuscles were found in every case that had rabies, and in none that did not have it; in a case of rabies paralytica they were very rare in the cornu ammonis, encephalon, and cerebellum; the number of corpuscles found has no relation to the severity of the disease; the corpuscles were mostly intracellular, but in a few cases were found outside of the cells; there were many of smaller size in the Gasserian ganglion and the spinal ganglia—*La Riforma Medica*, June 8, 1904.

Instrumental Dilatation of the Neck of the Uterus in Pregnancy and Parturition.—R. de Seigneux presents a modification of the dilator brought out by Bossi, with the use of which he has had excellent results in a series of twelve cases. Bossi was able to produce dilatation with his instrument in fifteen minutes if haste was necessary, or in two hours if there was no haste. But there was danger of laceration of the uterus and the process was exceedingly painful. With the author's modification, which has a pelvic curve such that the dilatation is made in the plane of the axis of the pelvic strait, the pain is slight, no anæsthetic is necessary, there is no danger, and he has always delivered a living child. The instrument has arms of different sizes and shapes, which can be changed as desired. The arms can be introduced separately, as in obstetric forceps, and connected afterward. The instrument is simple, easily sterilized, and fulfils all surgical conditions.—*Archivio di Ostetricia e Ginecologia*, May, 1904.

The Therapeutic Value of Nephrotomy.—Guyon enuerates several cases in which nephrotomy has been performed with great benefit to the patient. One of the patients whose history is given was a girl of sixteen years. She was attacked by a severe cystitis of suspicious origin. There was, indeed, a beginning pulmonary tuberculosis. The urine had no bacilli. Nevertheless, lumbar pain developed and increased in severity The girl had a hectic fever. The left kidney was very painful on pressure and increased in volume. Nephrotomy was done. Miliary abscesses were disseminated throughout the renal cortex. Improvement followed immediately. An abundant flow of urine was effected by the renal incision. The general condition was improved. The patient is now well. As soon as the renal opening is made the urinary functions are redeveloped very quickly. The incised kidney secretes urine and the fever ceases more or less quickly.—*Journal des Praticiens*, July 2, 1904.

The American Journal of the Medical Sciences, July, 1904.

Actinomycosis of the Tonsils.—Jonathan Wright emphasizes the importance of examining microscopically absolutely all tissue removed from the nose and throat in the routine of either hospital or private practice. This case which the writer reports was a boy of twelve years, whose tonsils were removed. He still remains well. Microscopical examination showed the characteristic club-shaped rays of the actinomyces group. The infecting germ had evidently lodged in a tonsillar crypt. In a very large number of cases the tissue changes can be traced directly to a carious tooth cavity. The lower jaw is more often attacked than the upper. Iodide of sodium has a very favorable effect upon the lesions of actinomycosis.

A Case of Meralgia Paræsthetica.—John E. Donley states that meralgia paræsthetica is the name given to a peculiar syndrome appearing most commonly, though not exclusively, in the distribution of the external cutaneous femoral nerve. In a large number of cases there are tingling and numbness, increasing in severity as the leg is used. Some patients complain of heat, others of cold. Sometimes the lightest touch is unbearable. There is marked diminution of sensibility to pain, touch, and pressure. The etiology of the disease is obscure. The pathology is a mooted question. Strychniæ sulphate seems worthy of trial in these cases, as its use has been followed by distinct improvement. Massage, followed by wrapping the limb in hot towels, is advisable. A mild, galvanic current supplements the above after a week. The limb should have complete rest. Counter irritation is harmful in these cases. Resection of the nerve in obstinate cases is advised.

The Influence of Daylight on the Progress of Malaria.—Gunni Busck enumerates the following points: The special effect of quinine in malaria can hardly be explained as a direct outcome of its toxicity with regard to plasmodiæ, although this undoubtedly is very considerable, and if we look for an explanation of this effect we must not leave out of consideration a peculiarity so distinct as the power to make microorganisms sensitive in relation to light. Quinine preparations have decided sensitiveness-arousing qualities. Paramæciæ, which are placed in solutions of quinine of 1:20,000, first die after about five hours when standing in the dark, while they are killed in eight minutes if placed in sunlight, under conditions which generally have no baneful effect upon paramæciæ. According to experiments, light, even after having passed through a layer of animal tissue, can exercise its microbicidal effect upon the sensitive-made organs. The depth at which it will be possible to obtain an effect will, among other things, depend upon the intensity of the light. The tissues of the human body are pellucid, and if only a comparatively small part of the body surface is exposed to light, the blood and the plasmodiæ with it, will, on account of its continuous circulation, all the same be affected by the light. If these views are correct, malarial patients should be treated with sun-baths, or electric-light baths in addition to quinine, as it would seem that daylight can increase the favorable effect of quinine preparations upon malarial patients.

Surgical Scarlatina.—Alice Hamilton presents the following conclusions: There are about 174 cases of surgical scarlatina reported in the literature more or less in detail, and passing mention is made of many more. Operations and wounds of all kinds, as well as inflammatory processes, are supposed to predispose to scarlatinal infection. Surgical scarlatina is said to differ from medical scarlatina in five ways: (1) The large number of adults attacked. (2) The shorter period of incubation. (3) The mild angina or absence of angina. (4) The fact that the eruption begins at the wound or in some other unusual region. (5) The slightly precocious desquamation. Proof of the existence of a special form of scarlatina occurring in connection with wounds rests upon the large number of cases recorded in which an eruption resembling that of scarlet fever followed some injury, and upon the frequency of epidemics of scarlet fever among surgical cases in the days before complete isolation of fever cases was practised. Careful examination of the reported cases confirms the view held by most French writers, that the eruption in question is often due to septic infection, and is not scarlatinal, and that the variations of so-called surgical scarlatina from the typical form of scarlet fever are not due to the unusual mode of infection, but to the difference in the infectious agent. In the cases in which the disease was undoubtedly scarlatina, there is no convincing evidence that the relation between the wound and the scarlet fever was anything more than one of coincidence. The statistics of epidemics of scarlet fever in surgical wards in hospitals lack the necessary comparative statistics as to the same disease in the medical wards. There is, as yet, no convincing proof in the literature that surgical scarlatina is anything more than scarlet fever in the wounded.

The General Management and Therapeutics of Nephritis.—Beverley Robinson declares that it is only rarely that he meets acute nephritis which is typical according to the textbooks. The great number of cases are grafted on a former process, which has existed for some time, and which has probably been caused in the first place by harmful and irregular modes of life, or become developed during the course of some infectious disease. The first thing to do in all cases of nephritis in which there are acute symptoms is to put the patient to bed. The underclothing should be of wool, and the patient should lie next to blankets. Two principles should be kept in view: Physiological rest, so far as possible, to the diseased organ, and relief of function, especially through the action of skin and bowels. Small quantities of food should be given, and solely in liquid form. A milk diet should be insisted upon, but with certain limitations proceeding from common sense and experience. After a day or two, water in abundance may be freely given. When the bowels have been well moved, a hot wet pack properly applied to cause perspiration without danger of chill, should be insisted upon. High rectal irrigations promote diuresis and neutralize toxic substances from the intestinal tract irritating to the kidneys. In threatened uræmia nitroglycerin will often relieve the situation. In a real uræmic seizure, bloodletting will sometimes be the only way of saving life. When the patient begins to sit up, iron is desirable in moderate doses. When there is an excessive degree of œdema, it is desirable to use the lancet. It is relatively easy to point out the dangers of unwise medication, but it is difficult to say what medicinal remedies are useful in ameliorating or curing the disease. Chronic nephritis is so insidious that we know of no really efficient drugs for this condition. In general, nephritic patients are better off without alcoho.

in any form. In the case of much sleeplessness, the writer prefers the bromides to chloral. The effects of subcutaneous injections of saline solutions are not as desirable as those derived from infusions or enemata, according to the writer's belief. It seems desirable to suppress entirely the use of salt in the dietary of those affected with acute or chronic nephritis. Theobromin is of great value as a diuretic to diminish albuminuria, and to benefit the general condition of the patient.

Primary Tuberculosis of the Breast.—Brooke M. Anspach states that mammary tuberculosis is rare. There are no cases of primary tuberculosis of the breast on record in which the diagnosis was made after autopsy. The importance of this affection lies in the possibility of its transmission from the mother to the nursing child. As a secondary lesion, it has no special significance. Tuberculosis of the breast occurs in either a confluent or a disseminated form. The confluent abscess in the presence of mixed infection is the usual variety. An abscess purely the result of the tubercle bacillus, the so-called "cold abscess" is quite rare. The skin remains unbroken and there are no fistulæ. The axillary glands are not involved. The disseminated form is so rare that it is denied by some authors. In suspected cases the mammary secretion should be stained for tubercle bacilli. The disease in itself is favorable. The result depends upon the existence of visceral complications. Although simple evacuation and curettage or extirpation of the diseased nodules alone has sufficed in some cases, the gravity of the disease usually demands amputation of the breast, and the removal of enlarged axillary glands.

Annals of Surgery, July, 1904.

Some Remarks on Tumors of the Chiasm with a Proposal How to Reach the Same by Operation.—Otto G. T. Kiliani reports briefly such a case. He concludes that the only rational way of getting at the chiasm is in the following manner: A Wagner flap is formed on the frontal bones with true omega shape, the base of which lies about half an inch behind the suture coronaria, the indentation of the omega comes to lie exactly in the median line, to avoid, if possible, the opening of the sinus frontalis. The dimensions of the bone flap thus formed are in the median line 5 inches, the lateral diameters being 5½ inches, the width 7 inches, and the base where it is broken off, 3½ inches. The skin incision severs the temporal artery on both sides. The opening of the skull is made with a Sudek's fraise with electric motor, beginning at the base of the flap, the fraise is then led on forward, following closely the line of the omega formed in such a manner that the distance of the horizontal branches from the orbital margin is three-quarters of an inch, then going upward to describe the indentation for the purpose of avoiding the sinus, thus reaching a height of one and a half inches from the root of the nose. The other half of the flap is symmetrical.

Suture of the Brachial Artery.—Gaston Torrance reports the case of a boy, seventeen years old, whose arm was badly crushed about midway between the elbow and shoulder by the wheels of a car. The muscles on the outer side of the arm were badly lacerated, exposing the bone. He was brought to the hospital and the wound was dressed. At the end of a week the arm began to bleed profusely. Upon opening the wound, the artery showed a funnel-shaped ulcer which had perforated, the opening being about the size of the point of a pencil, and at every pulse-beat the whole of the blood was forced out through this opening. There was no sign of a radial pulse and the arm was cold and œdematous and of a dark color. His first suture was introduced with the arm extended, but tore out when tied, and he saw it would be necessary to flex the arm and keep it in that position. He used a small, full-curved intestinal needle with fine silk, introducing it as a purse string, and upon tying it found that it completely controlled the bleeding. Only one suture was used. A portion of muscle was dissected up and grafted over the anterior part of the artery. Five hours after operation the radial pulse was strong. He was kept in bed about two weeks and the arm was kept in splint for two months. A good result was obtained, the patient being able to use his arm.

Pyæmic Glanders in the Human Subject.—J. Clark Stewart reports such a case, which seemed worthy of record from its most fortunate termination and the extreme rarity of laboratory glanders. The points of especial interest were (1) its origin from two cases of most virulent pyæmic glanders in young men owing their infection to contact with diseased horses. Both cases began with symptoms resembling typhoid fever, rapidly passing into those of sepsis. Both died on the seventeenth day with multiple abscesses of the skin and subcutaneous tssue, the skin lesions being so numerous as to excite the suspicion of smallpox. (2) The incubation period was six days, figuring from the only chance of infection, the patient having made the autopsy upon the inoculated guinea-pig when she had an open wound on her finger. (3) The absence of the lesions of the skin and mucous membranes which are so common in most cases of glanders and the limitation of the original foci to the voluntary muscles. The points aimed at in the surgical treatment of the case were, first, delay in hopes that the foci might become encapsulated by inflammatory changes in the surrounding tissues, and that the patient might become, as far as possible, immune by the manufacture of her own mallein. Second, the avoidance of local implantation of bacilli mallei upon wound surfaces when foci were eradicated. Several methods aiming at the prevention of inoculation were suggested, including the actual cautery; but the use of 95 per cent. carbolic acid and alcohol on all cut tissues before exposing them to pus contact proved entirely satisfactory in preventing further local lesions, and allowed the wounds to heal promptly except where the packing and anatomical conditions favored the pesistence of a sinus. A complete but tardy recovery ensued.

The Anatomy and Surgery of the Internal Derangements of the Knee-joint.—Benjamin Tenney considers in detail the anatomy of the knee-joint and gives the chief reasons why the knee is the most frequently deranged of all the joints in the human body. Among these 150 cadaveric joints were found examples of nearly every "internal derangement of the knee-joint" which has yet been described. A classification of internal derangements according to their frequency in his series of cases would be as follows: (1) Tabs from the lubricating apparatus. The infrapatellar pad was the most frequently injured structure, and was noted in one hundred joints. In twenty-two of these one hundred there were seen tough fibrous tabs, pedunculated and attached to the infrapatellar pad; these tabs were without fringes and were never found crushed. Where these form a mechanical obstacle to the perfect working of a joint, they can be removed only by mechanical means and the only treatment is operation. (2) Erosion of articular cartilage. A frequent injury found in these joints was seen on the articular cartilage at the back of the upper surface of the external tibial tuberosity, the damaged area usually measuring a little over a centimeter in diameter, and always rounded. It showed all stages from a shallow cracking or "crazing" of the smooth cartilaginous surface to bare bone with a few tufts of fibrous tissue projecting from the edges and from the small centers inside the bare space. Another pathological condition was a loss of cartilage along the inner border of the patella, and is probably one of the least disabling of all the joint injuries found. (3) Damaged and displaced semilunar cartilages. Some of the most striking injuries were found in connection with these cartilages, and he groups them as follows: Joints with both semilunars damaged, 15; joints with damaged external and normal internal semilunars, 13; joints with damaged internal and normal external semilunars, 14; total, 42. Of these 42 joints, 24 were noticed as showing some of the marks of inflammation or degeneration of articular cartilage. The important thing was the dryness and consequent friction which was always present in some stage of the condition. The first noticeable effect of friction may be expected to show in the appearance of fine fringes or strands at the edges of the semilunars after the cartilaginous layer is worn away. Or one or both of the semilunars may be caught between the moving femur and tibia and split longitudinally somewhere between their free edge and their capsular attachment. Long continued friction must ultimately result in ligamentous damage. (4) Ruptured ligaments. If the femoral condyle overrides and settles down behind its semilunar, and extension occurs while the joint is loaded heavily enough, the cartilage may be torn from its peripheral attachment and folded over into the notch. Otherwise, the dislocation will be reduced with a "snap," which accounts for the name "jerking" or "trigger" knee. One hundred and twenty-eight operations on the semilunar fibrocartilages have been gathered from the reports of forty-seven operators. The internal was injured 113 times, the external but fifteen. The exact diagnosis of semilunar injuries is seldom attempted before opening the joint. The opinion is expressed that removal of the damaged cartilage is preferable to suture. Ligamentous damage of any degree must be followed by swelling. Three methods of treatment for these acutely distended joints are in use: First, Rest followed by massage and movement. Second, Aspiration, repeated, if necessary, to relieve the distension and remove a material which would discourage movement and encourage the formation of adhesions. Third, Incision with drainage. (5) Free and loose bodies. There were but two such among his specimens. Operative removal of these free bodies is the only treatment to be considered to-day.

Book Reviews.

The Mothers' Manual, A Month by Month Guide for Young Mothers. By Emelyn Lincoln Coolidge, M.D., Visiting Physician of the Out-patient Department of the Babies' Hospital, New York; formerly House Physician of the Babies' Hospital, New York; Physician in Charge of the Babies' Clinic of the Society of the Lying-in Hospital of the City of New York. Illustrated. New York: A. S. Barnes & Company, 1904.

The author's wide experience in the care of infants, has well fitted her for the preparation of this book, which forms one of the series of "The Woman's Home Library," edited by Margaret E. Sangster. The manual is full of practical hints for mothers. The first twelve chapters are devoted respectively to the first twelve months of the baby's life. But the child's life is followed still further in the later chapters—up to the seventh year. Just the questions which any mother needs to ask are answered here, for the book is eminently practical, and deals with every-day matters that every mother has constantly to meet. The closing chapters discuss Backward Children and Proprietary Foods.

Histoire de la Coca, la Plante Divine des Incas. Par le Docteur W. Golden Mortimer, Membre de l'Académie de Médecine de New York, Membre de la Société Médicale de l'État de New York, de l'Académie des Sciences, du Muséum Américain d'Histoire Naturelle, Ancien Chirurgien du New York Hôpital de Rhinologie et de Laryngologie, etc. Traduction de la deuxième édition (1902). Par H. B. Gausseron, Professeur agrégé de l'Université de Paris. Paris: A. Moline, 1904.

This volume, which is a translation, presents the results of the most exhaustive and painstaking researches. The author considers the history of coca, its physiology, the chemical composition of the coca leaf, and its alkaloids; the physiological effects of coca—its influence on muscular energy, on the nervous system, on the voice, and on respiration, and its rôle in nutrition. The author finally gives the observations concerning coca of numerous physicians with whom he has corresponded in order to gain their views on this subject.

Modern Ophthalmology. A Practical Treatise on the Anatomy, Physiology, and Diseases of the Eye. By James Moores Ball, M.D., Professor of Ophthalmology in the St. Louis College of Physicians and Surgeons. With 417 Illustrations in the Text and Numerous Figures on 21 Colored Plates. Philadelphia: F. A. Davis Company, 1904.

This is really a very handsome volume; a decided credit to the publishers as well as to the author. The book is one of 820 pages. The text is preceded by a table of contents and lists of illustrations. Many of the illustrations are original. They are excellently drawn and are reproduced in a most satisfactory manner. The illustrations are well chosen and properly placed to elucidate effectively the text.

The work is divided into twenty-five chapters. The first two chapters are occupied by a description of the development and anatomy of the eye. Then follow a chapter on the physiology of vision and another on the examination of the eye. Diseases of the various parts of the eye are next considered. Anomalies of the muscular apparatus are discussed in Chapter XX. "Ocular Manifestations of the Nervous Diseases" have received liberal mention. A chapter is devoted to a consideration of "Preparation for Ophthalmic Operations." The hygiene of the eyes is discussed in Chapter XXIV. A short chapter, the concluding one of the volume, is devoted to a description of methods employed in the microscopical examination of the eye.

In the chapters on diseases of the various parts of the eye the lists of diseases are very complete and the consideration of the various topics sufficiently comprehensive. Full credit is given to the various writers whose theories and methods are mentioned, but there is no bibliography. The omission of this feature does not affect the value of the work to the student and to the general practitioner, but might be felt by the specialist. The various operative procedures sufficient for dealing with the majority of the problems that present in the surgery of the eye are clearly described and are given their proper value. The arrangement of the volume is systematic. Superfluous matter seems to have been rigorously excluded. One of the valuable points of the work is a comparison of the diagnostic points of diseases that resemble each other, arranged in parallel columns.

The author may be congratulated on the excellence of the work that he has produced. It will undoubtedly be appreciated by the student, the general practitioner, and the specialist.

Uric Acid. an Epitome of the Subject. By Alexander Haig, M.A., M.D. Oxon., F.R.C.P. Physician to the Metropolitan Hospital and the Royal Hospital for Children and Women. Philadelphia: P. Blakiston's Son & Co., 1904

In this little book Dr. Haig summarizes in very readable form his well-known theory of the causal relation of uric acid to most of the ills of human flesh. We say "well-known" theory because every one has heard of it, but that does not mean well understood, and it is to increase the understanding of it that the author has written his book. There is little to be said in review of the work, for it is simply a restatement, in abridged form, of what is contained in his larger treatise on "Uric Acid as a Factor in the Causation of Disease," which was noticed in these columns a few months ago. Those who wish to know exactly what Dr. Haig's theory is and the arguments in support of it can do no better than read this book. Then, if they are converted to the author's views or if they want to go still deeper into the subject, they can turn to the larger work.

A Textbook of Physiology. By Isaac Ott, A.M., M.D., Professor of Physiology in the Medico-Chirurgical College of Philadelphia With 137 illustrations. Philadelphia: F. A. Davis Company, 1904.

This is not a treatise on physiology, but simply a textbook in which the main facts of the science are stated briefly and without argument. Little space is given up to an account of laboratory experiments, and when these are mentioned their technique is not described at any length. The author is rather careless as a writer, and it would tax a grammarian's ingenuity to parse many of his sentences, but the matter of the book is good, and faults of style are unfortunately so common in scientific works that they seldom excite comment. We are sorry to note however, that Dr. Ott speaks of the so-called physiological salt solution as a normal saline solution. A physiologist should be enough of a chemist to know better than that, and, knowing, he should be too careful in scientific statement to make such a slip. But, in general, the book is to be commended as a guide for the student and a useful textbook to supplement the didactic lectures of the class-room.

Graves' Disease with and without Exophthalmic Goiter. By Dr. Wm. Hanna Thomson. Physician to the Roosevelt Hospital; Consulting Physician to the Manhattan State Hospitals. Formerly Professor of Medicine at the New York University Medical College, etc. New York: Wm. Wood & Company, 1904.

This brochure is made up largely of the clinical histories of forty-two patients with exophthalmic goiter and of twenty-eight patients without goiter, with the author's deductions from his study of these histories. No attempt is made to consider the subject of Graves' disease exhaustively. Under "Symptomatology" the author says that "the distinctively characteristic symptoms of Graves' disease are twenty-eight in number," but he probably does not mean exactly that, as at least twenty-five of these twenty-eight are no more characteristic of Graves' disease than they are of many other diseases. We venture also to question the correctness of labeling a symptom complex Graves' disease in which occurs neither exophthalmos nor enlargement of the thyroid gland. Unquestionably, Graves' disease occasionally occurs without one or the other of these symptoms, but there is no Graves' disease if both are absent. It would be quite as legitimate to describe paralysis agitans and enumerate all the symptoms save tremor and immobilization of the body. Dr. Thomson refers to "paresis" as one of the distinctive symptoms, which we regard as unfortunate nomenclature, as it is used synonymously with myasthenia or amyosthenia. The sensation of giving away of the knees or other joints that occurs in such diseases as neurasthenia and exophthalmic goiter should not, we believe, be spoken of as a "paresis," for in reality it is not a partial paralysis.

Dr. Thomson is of the belief that disease of the thyroid gland has no primary relationship to Graves' disease, and that is the view which it would seem from an examination of the literature is most widely accepted at the present time. The section of the book that we commend as most worthy of careful attention is that devoted to treatment, although we do not agree with the reasoning upon which the author says it is founded, viz., "the dependence of the disease upon what is ingested into the alimentary canal." Proper dieting, the author holds, is the most important feature of the cure, fermented milk and elimination of animal food the *sine quâ non*. The medicinal treatment consists in the administration of gastrointestinal anteputrefactives, mercurials, castor oil, bismuth, subcarbonate, naphthol bismuth salicylates, benzoates, etc. Surgical interference is deprecated, and the matter of surgical treatment is given scant consideration.

Society Reports.

MEDICAL SOCIETY OF NEW JERSEY.

One Hundred and Thirty-eighth Annual Meeting, Held at the Hotel Chelsea, Atlantic City, N. J., June 4, 6, and 7, 1904.

THE PRESIDENT, DR. HENRY MITCHELL (ASBURY PARK), IN THE CHAIR.

Progress of Ophthalmology and Otology.—Dr. TALBOT R. CHAMBERS of Jersey City read this paper. He said that although the past year had been marked by scientific research, there was but little to report in the way of methods of treatment and of new operations with the exception of the operation for the removal of the lacrymal canal. Dr. Edward Nettleship, in writing on "Eye Changes in Relation to Renal Disease," said that he felt sure that there was but one sort of renal retinitis, and that the many varieties and changes seen indicated only different stages and degrees of general œdema, exudation, and degeneration. Dr. Elschnig had reported on 209 cases of nephritis and stated that the importance of the retinal changes as regarded the prognosis of life were as follows: Of 74 patients with normal interior of the eye, 3 died within six weeks from nephritis; of 60 patients suffering only from arteriosclerosis, 4 died within six weeks and 6 within six months; of 34 patients without pathognomonic retinal changes, 16 died within six weeks and 17 within six months. The high mortality of those cases with retinochoroiditis albuminurica was especially noted. All 6 patients died within six weeks after recognition. Major Henry Smith gave a report of 8,500 cases of cataract extraction, 6,500 of which were extracted in their capsules. This method of operation practically eliminated iritis and after-cataract and was in every way more desirable. The operation was performed by making an incision at the corneoscleral junction and at once taking out the speculum. The upper lid was then raised with a hook while with the thumb the lower lid was depressed. This controlled the orbicularis, which was in nearly all cases the cause of the loss of the vitreous. Dr. W. E. Gamble had given a statement of our present knowledge of the architecture of the cerebral visual apparatus in the light of the neuron theory and the later clinico-pathologic investigations. Dr. H. J. Woodward had given a *résumé* of the ocular complications of mumps. Here the wide range of eye diseases was both surprising and interesting, embracing abscess of lids, conjunctivitis, keratitis, iritis, transient interference with vision and accommodation, and one case of atrophy of the optic nerve. Dr. Charles A. Oliver, in writing on the treatment of gonococcal conjunctivitis, named as the chief requirements free and sufficient, but gentle, cleansing; early and full atropine dilatation; lowering the vitality of the invading cell form by ice compresses; maintenance of the vitality of the organ where there were trophic disturbances by the application of heat; destruction of the intruding germ by nitrate of silver; local and general issolation with treatment of similar infections of other mucous surfaces. Dr. Arnold Knapp, in a paper on the "Influenza Group of Bacteria in Conjunctivitis, Especially in Trachoma," concluded that: (1) There was an influenzal conjunctivitis without other manifestations of influenza. (2) The Koch-Weeks bacilli were not identical with the influenza organism. (3) The Muller trachoma bacilli were found in 8 out of 120 fresh cases of trachoma which he had examined. (4) This organism could not be differentiated from the true or pseudo-influenza bacilli (5) It seemed probable that its presence in these cases of trachoma was accidental. Dr. M.W. Zimmerman, in writing on "Ocular Headaches and Other Ocular Reflexes," stated that out of 2,000 refraction cases 1,427 presented some form of headache. Dr. Frank Allport had showed the necessity for annual systematic examination of school children's eyes, ears, noses, and throats. Otology was slowly making its way to a similar position with other special branches. Dr. J. A. Spalding, in a paper on "Tinnitus," had adduced the theory that if the perception of the tone of the tinnitus was pleasant to the patient when sympathetically vibrated by musical instruments, the tinnitus was labyrinthine; if unpleasant, harsh, and sensitive, then the tinnitus was due to obstructed condition—foreign bodies, cerumen, tympanic effusions, etc. This opened a new field in the treatment of this obstinate affection. Dr. P. D. Kerrison had concluded that in the operation on the mastoid process the antrum should always be approached from the nearest point upon the mastoid cortex, which in the great majority of bones was the small triangular space just behind the spine of Henle This point furnished a guide to the site of the antrum, and also gave fairly accurate data as to the depth beyond which it is not safe to proceed. The depth of the antrum is always less than the length of the postero-superior wall of the meatus; in the majority of bones it is not over 12 mm. The depth of five-eighths of an inch was regarded as the extreme limit of safety. Dr. E. Stangenberg in 1,000 cases of diphtheria found 24.3 per cent. with ear disease, and the intensity of the diphtheritic process seemed to stand in no constant relation to the occurrence of the ear disease. Dr. C. W. Richardson's paper on "Osteomyelitis of the Temporal and Adjacent Bones of the Skull" was very instructive, and also much that had been written on "Sinus Thrombosis," especially Grunert's contribution to infectious thrombosis of the bulb of the jugular vein and on the question of its operative treatment.

Report on Progress of Rhinology and Laryngology.—Dr. F. C. ARD of Plainfield, N. J., said that a review of the literature of the past year showed abundant evidence of progress in our knowledge of diseases of the nose and throat. Dr. Walter J. Freeman, in a paper on the "Diagnosis of Frontal Sinusitis" called attention to the symptoms of late morning headaches, fulness over the eyes on leaning over, exquisite tenderness at the inner angle of the orbital roof, and most important the discovery of mucopurulent secretion at the peak of the vestibule. Cases of obstinate asthenopia not relieved by glasses should direct attention to the nasal sinuses. The morning is the time favorable for detecting pus from the frontal and ethmoid and the evening from the antrum and sphenoid. Tilley, in a paper on "Suppuration of the Maxillary Antrum," reviewed the causes and symptoms of this infection and recommended transillumination as valuable in confirming suspicions founded on other symptoms. He recommended alveolar drainage in those cases in which the duration was of months instead of years; in cases of long standing radical operation —opening in the anterior wall of the antrum and removal of portion of the inner wall. Luc of Paris gives three methods of reaching the ethmoid cells, and Coakley has described an easy method of entering the sphenoidal sinus for diagnostic purposes and has given the symptoms which should indicate the necessity of such a diagnostic procedure. Dr. Beaman Douglas, after the study of a large number of operations on the cadaver, concluded that intranasal operation on the frontal sinus was attended with considerable danger for reasons which he had explained at length. The submucous injection of paraffine, injected cold into the inferior and middle turbinated bodies, was said to give immediate results in atrophic rhinitis. Moure and Brindel spoke highly of this treatment and reported the results in seventy cases. Dr Harmon Smith reported six cases of death from hemorrhage following tonsillotomy, and after enumerating the causes, suggested as means of control Paquein or galvanocautery, torsion by means of ligature through the tonsillar folds, and twisting by means of artery forceps. He noted three cases of alarming hemorrhage in which he had used the Mickulicz-Stoerk hæmostat successfully. Dr. J. S. Richards had described a new method of removing

septal spurs. An incision is begun above and posterior, carried down to the floor of the nose, then forward and anterior to the spur and carried upward. The mucous membrane was then deflected upward and the spur removed. The flap was then replaced. The therapy of hay-fever has received a new impetus by the discovery of a new serum by Dunbar. Lupus vulgaris of the respiratory mucous membrane has been successfully treated at the Finsen Light Institute, Copenhagen, and scarification was no longer employed. In regard to operative treatment of stenosis of the larynx following intubation and tracheotomy the prognosis in complete laryngectomy seemed improved, owing to the improved surgical procedures employed. Many cases of recovery had been reported during the past year. The literature of laryngeal tuberculosis had given us the earliest signs of this disease, and Lockard had succeeded in relieving the suffering of the most advanced cases by division of the posterior commissure in the median line, by division or removal of the epiglottis, and by tracheotomy. Godskesen had contributed a valuable article on laryngeal tuberculosis during pregnancy.

The Treatment of Angiomata by Boiling Water.—Dr. John A. Wyeth of New York read this paper. He said that arterial angioma or circoid aneurysms and venous angioma or cavernous nævus had given better results than capillary angioma. He reported a number of cases of inoperable cavernous nævi, all of which were successfully treated by coagulation with water at a high temperature. After a few injections coagulation was usually effected and the hardened mass underwent granular metamorphosis and disappeared by absorption. In his experience there had been no escape of coagulum from the region of operation into the general circulation, and he deemed it proper to take every precaution for the prevention of such an occurrence. Only a small quantity of water was required for the injections, about five minims for each puncture. Compression on the side nearest the heart in venous angioma was always advisable until coagulation was effected. If the tumor was on an extremity with room enough between the neoplasm and the trunk the application of a tourniquet was advisable. In using this agent for the consolidation of tumors one must be careful not to produce necrosis of the part by having the water too hot or by applying too much to a part. One was apt, however, to put the water in at too low a temperature. Taking the instrument out of the boiling caldron, filling it, adjusting the needle and applying it meant that the water had cooled considerably. The operator's hands should be protected and all parts of the patient's body except that part which was to be injected. An assistant with a sponge saturated with cold water should always be at hand in case the injected water should regurgitate through the puncture. The capillary variety were liable to break down under the heat and to become infected and suppurate, leaving a scar which, though not so large as the original, would subsequently have to be removed. He carried the needle through the sound integument about one-eighth to one-sixteenth of an inch from the edge of the growth, pushing the point to about the center of the neoplasm and then injecting the water forcibly until the angioma began to swell and turn gray. In the after-treatment a simple dressing of dry gauze was sufficient.

Dr. W. L. Rodman of Philadelphia said that he had used Dr. Wyeth's method in two cases, which unfortunately were of the capillary variety. He had followed Dr. Wyeth's technique as far as possible, but his results were not all that could be desired, owing to the variety of the tumors and to the fact that he had not been able to keep the patients under his care long enough to determine just what results were possible. Where it was feasible he thought excision the best method, but where there were tumors that resisted ordinary methods he thought the injection of boiling water a valuable means for treating them.

Dr. Wm. J. Chandler of South Orange asked Dr. Wyeth if any fatal cases had been reported as the result of the treatment outlined. He said that Dr. Bulkley had had one fatal case.

Dr. John A. Wyeth replied that he had not heard of a fatal case in this country. In London a child had died seemingly of pulmonary infarctions of some kind. The patient had already some pulmonary trouble. Dr. Wyeth agreed with Dr. Rodman that where neoplasms could be thoroughly removed by excision with proper approximation and the employment of aseptic precautions this was the proper method. He used this method with neoplasms larger than one inch in diameter. He had known two children who died in one day in one hospital and at one clinic in New York under chloroform and this had made him cautious. He preferred to operate upon children by this method without a general anæsthetic, but, if an anæsthetic was to be given, ether was preferable.

Progress in Medicine and Therapeutics.—Dr. Philip Marvel of Atlantic City presented this paper, in which he considered the advances in medicine during the past year, and, of these, those along the lines of infectious and parasitic diseases stood out most prominently, as also did investigations of the bodily metabolism. Much had been done and results obtained by the application of the *x*-rays, but of the element radium it was as yet too early to speak, except that it promised to be of great value in the treatment of certain lesions of the skin and in malignant processes. The founding of the Phipps Institute in Philadelphia for the study and treatment of tuberculosis marked a mile-stone in the progress of the study of this infection. Protozoan pathology had attracted much attention during the past year. Real progress had been made during the past year in the application of drugs as remedial agents. Adrenalin, while a comparatively new production, was now thoroughly understood, and the conditions were certainly increasing in which it could be used with benefit. Acetozone possessed marked germicidal activities, was innocuous, was rapidly absorbed, stimulated the urinary secretions, and was thrown off as hippuric acid. Argyrol was said to contain 30 per cent. of metallic silver, and possessed the power of penetrating deeply into the submucosa. Aspirinol had been employed as a substitute for the salicylates, was almost insoluble in water, and had little taste. The reports on the use of cerebrin in epilepsy were apparently most satisfactory. The intravenous injection of collargol in the treatment of septic conditions, as originally introduced by Crede, had proven efficacious in a reported case. The subject of serum therapy had developed so rapidly and into such a complex affair that it was difficult for those in private practice to master its many phases. Antistreptococcus serum, according to laboratory experiments, was applicable only for the germ or germs for which it was prepared; it acted by not neutralizing the toxins but by destroying the germs themselves. Under the exhibition of tetanus antitoxin the mortality has been reduced from 80 per cent. to between 40 per cent. and 50 per cent. Antithyroidin injected subcutaneously has been used with some success in Basedow's disease. The literature on the use of the *x*-ray has been enormous. The best results have been obtained in rodent ulcers and cutaneous epithelioma. In lupus the results have been almost as favorable as in rodent ulcer. Radium emanates three different kinds of rays, one which travels at the rate of 100,000 miles per second and has already been recognized as likely to have a useful place in the treatment of certain diseases, particularly those that lie near the surface of the body.

Report of a Case of Albuminuria.—Dr. Philip Marvel reported the case of a boy fifteen years old, weighing 118 pounds, who had had the following diseases in the following order: Whooping-cough, measles, bronchial pneumonia twice, influenza, enterocolitis of an aggravated type, scarlet fever, typhoid fever, followed four

months thereafter by an attack of influenza complicated by malaria, in which both the Pfeiffer bacillus and the malaria plasmodium were found. In his early years he had been bitten by a dog, following which a condition of general sepsis ensued, and also after vaccination he was quite ill, with high temperature, delirium, etc. He has been subject to severe angina. Culture studies from a few of the attacks show principally streptococci. Frequent examinations of the urine were made after the attack of typhoid and of influenza and malaria, which gave a slight showing of albuminuria after the latter only. In October, 1903, he had a slight attack of what seemed to be simple tonsillitis. One week thereafter a specimen of urine was examined which exhibited slight albuminuria, no casts and no nephritic débris. A specimen was examined every few days thereafter, and each time with increasing evidence of albuminuria, casts, and renal débris, *i.e.* epithelia cylindroids, leucocytes, etc. From this time on, they were never entirely absent. The albuminuria has not changed in the main, though it has changed in the particular in that at times the specimens voided immediately before or after rising showed but mere traces, which was likely to be followed by a volume occupying at least one-half the space in the tube. Estimates made from time to time showed a varying estimate of from one-eighth of a gram to two grams to the litre. The estimate of urea has varied from 5.7 to 16.5 grams per day, and diet had but little or no influence upon the progress of the case. Rest, likewise, seemed to have but little effect. He had rather a liberal ménu, restricting only red meats, pastry, desserts, and raw fruits.

Some Abuses and Uses of Cardiac Stimulants.—Dr. W. Blair Stewart of Atlantic City gave a brief résumé of the too common practice of prescribing cardiac stimulants without carefully considering the cause and condition or when they should be used and when not. If cardiac stimulants were to be administered intelligently and correctly, it was necessary to understand the anatomy and physiology of the heart and circulation; promptly to diagnose and recognize all valvular irregularities and to reason out their effects; to recognize all causes having a direct and indirect effect upon the heart and to recognize acute and chronic processes; and finally to study the physiological action of each drug used. He said we should only use a cardiac stimulant when there was evidence of the heart failing to perform its proper function in keeping up an active circulation; we should stimulate in syncope, in failing compensatory cardiac hypertrophy, in certain valvular defects in which special drugs were indicated, in poor innervation of the heart, in extreme physical tire, in shock, and in many other conditions in which real heart weakness was present. If we subdivided the cardiac stimulants, we could classify them as (*a*) direct cardiac stimulants. (*b*) indirect cardiac stimulants, and (*c*) cardiac regulators. It was his desire to urge upon the profession the necessity of closer discrimination in the use of this class of drugs, a closer study of diagnosis and physiological processes, a systematic study of the physiologic and toxic action of each drug; and an application of a proper remedy in a proper place.

Gastric Ulcer.—Dr. E. F. Fogg of Bridgeton, N J., stated that the cause of round ulcer of the stomach was a matter that still perplexed physicians and pathologists. He said that our explanation at present as to the formation of gastric ulcer was that an interruption to the circulation of the blood through a given part of the stomach mucosa interfered with the nutrition of the tissue of the part and destroyed the power of the part to resist the action of the gastric juice. Just what produced the changes in the vessels of the mucosa that obstructed the flow of blood to the affected area was somewhat doubtful. It was claimed that such injuries as resulted from blows were prone to heal and resulted in ulcer only when there was an excess of hydrochloric acid present. Mechanical injuries, thermal and chemical irritation, might produce lesions in the mucous membrane of the stomach, but it was believed that very rarely, if ever, did such lesions produce typical round ulcer. It was worthy of mention that an injury of a tissue that would result in ulcer in the presence of a digestive fluid, might not result in ulcer in the absence of such a fluid It was probably that actual death of an area was not necessary to permit of its digestion, but that an injury to a part without death, by reducing the vitality of the cells, would allow the digestive fluids to act and thus give rise to ulcers. The most difficult feature of gastric ulcer to account for was its chronicity. It was believed by some that the chronic course was due to the presence of an excess of hydrochloric acid. We knew that a large percentage of the cases of ulcer of the stomach had an excess of hydrochloric acid. While most authorities did not mention specifically ingested food as an irritant that helped to keep up gastric ulcer, and as an agent which excited certain abnormal physiological and chemical conditions which prevented healing, he personally believed it to be a prominent factor in keeping up the chronic condition of the ulcer His reason for choosing this subject was to emphasize the importance of early diagnosis and prompt and vigorous treatment. The disease was very common. There were generally dyspeptic symptoms, such as nausea, vomiting, and eructation of gas, often a constant ache in the region of the stomach, attended with circumscribed tenderness. The ache was often made worse by pressure upon the sensitive area and was often increased by walking or jolting. Hemorrhage was an important symptom, but its absence meant nothing. In those cases in which hyperchlorhydria did not exist, it was supposed by some that an excess of hydrochloric acid was at one time present and after initiating the chronic course of the disease had subsided. Many cases were treated as mere dyspeptics. This was very unfortunate, for in many cases tissue changes took place in and around the ulcer, which rendered healing long and difficult and sometimes impossible. In a patient suffering from abdominal pain or distress or dyspeptic symptoms, one of the first conditions, because it is one of the most serious, that should suggest itself to the mind of the physician was gastric ulcer, and he should endeavor to determine whether or not it was present. The treatment of gastric ulcer was very simple. A regular restriction of the diet was most important. Every patient should be put to bed. Small quantities of liquid food might be given by the mouth, and small quantities of water. It was wise to withhold milk until the patient had improved somewhat. It was probably better to feed all cases from one to two weeks by the bowel, giving only water by the mouth. If vomiting persisted, even water should be withheld for a few days. Medication was of the least importance, though bismuth subnitrate in large doses, in connection with the dietetic treatment had given most satisfactory results. He thought the time was ripe for surgical measures to be more extensively employed in the treatment of gastric ulcer than in the past. The opening of the abdomen could be more commonly practised in unsatisfactory cases if for no other purpose than that of diagnosis. Until our technique was further perfected only those should be operated upon in whom the symptoms persisted notwithstanding the most thoroughly conducted dietetic treatment.

Dr. Joseph Tomlinson of Bridgeton, in discussing Dr. Fogg's paper, alluded to the fact that ulcer of the stomach was a very common disorder, and that many sudden deaths from perforating ulcer went unrecognized. Cancer might also develop in the cicatrix of an old ulcer In 187 consecutive cases observed at the Massachusetts. General Hospital there were only six perforations, while in 500 cases observed in a London Hospital, perforation occurred in 10 per cent. Cancer, gallstones, and even appendiceal trouble might simulate gastric ulcer very

closely in symptomatology. Indeed, in many cases an absolute diagnosis could only be made by means of an exploratory incision. In view of the many dangers attendant upon delay, this method of diagnosis was advocated, and also because of the fact that the great percentage of cases, both of cancer and ulcer, existed near the pylorus, the part of the stomach most accessible, and most easy of inspection. In his own experience, one reliable symptom in early diagnosis was that of abdominal rigidity. This offered almost positive evidence of perforation. In the treatment of ulcer of the stomach, medical measures were in many cases disappointing, best results being obtained by rest and the withholding of food. The contractions and cicatrices resulting from ulcer of the stomach often gave more pronounced symptoms than the ulcer, and here also surgery could find a larger field of action.

Gastro-uterine Disease.—Dr. Joseph M. Rector of Jersey City said that intricate as might appear the underlying conditions which were responsible for the complex mass of symptoms referable to gastro-uterine disease, impossible as might seem the barriers which surmounted the attempt to unravel these pathological difficulties, yet they all became simple when one systematically investigated them. He said that if we examined a woman when her first symptoms with which we are all familiar appeared, we might find a simple lacerated cervix uteri, a prolapse of one or both ovaries, a retrodeviated uterus, with or without adhesions. We might find the entire uterus inflamed or its endometrium alone diseased, a small fibroid might be felt upon the fundus or upon the exterior wall, or a purulent discharge might tell the story of an infection that was the starting-point of disease. The epigastrium was tender over the stomach, constipation and a tympanitic enlargement of the abdomen marked the beginning of gastric or intestinal indigestion. As time passed a worse condition of affairs would ensue. Frequent vomiting, dyspepsia, acid eructations, and cardialgias appeared. Hydrochloric acid of the stomach was decreased, and sulphuretted hydrogen was present in excess in the intestinal tract, resulting in non-assimilation and anæmia. He called attention to the reflex paths which he had described, namely, the pneumogastric and lumbo-sacral nerves, branches of the cerebrospinal system which were in close connection with the sympathetic system—solar and hypogastric plexi. These sympathetic nerves contained vasomotor and secretory functions and, according to Rohrig, acted in a centripetal direction. Thus, it was easily to see how the reciprocity between the uterus and stomach was established. One of the main causes, then, of gastro-uterine disease was the close anatomical relationship existing between these two organs. The reflex nerve paths were the means of transmission; primarily, the disease effected the uterus, then, secondarily, reflex symptoms appeared which simulated gastric disorder. Peripheral irritation was undoubtedly an exciting cause, and that irritation might result in the production of reflex disturbance; and while the reflex neuroses were only symptoms, they were frequently productive of more distress than the organic disease from which they took their origin. When the necessity arose of explaining the correlation of symptoms otherwise than could be satisfactorily accounted for by the distribution of nerves we might describe the same by reason of existing statical factors between the two organs, stomach and uterus. In its normal position, the stomach is held in position by its ligaments and the surrounding organs. The uterus was held in position by its maintaining ligaments, the upper pressure of the levator-ani muscle and the intraabdominal pressure. The normal adjustment of both organs was accomplished by intraabdominal pressure. The equilibrium of these organs was destroyed whenever their volume was altered, the normal balance disturbed, or a change occurred in the adjusting force. The descent of the diaphragm disturbed the intraabdominal pressure and compensation became established by an equal outward expansion of the abdominal wall. If this change was not sufficient, the force exerted its increased action upon the greater curvature of the stomach, and pushed the organ upward until finally it might require the forward displacement of the intestine to meet the necessity of the changed intraabdominal pressure. The direction of the pressure now is from above downward and forward, and the result of this changed direction acting upon the uterus might cause either a procidentia or a retrodeviation. Again a large subinvoluted uterus might by its own weight and bulk fall downward and backward until an independent position of retrodeviation resulted. The reflex gastric symptoms were the result of pressure upon the sympathetic and hypergastric plexi, through the reflex nerve paths which he had described.

Vibratory Massage in General Practice.—Dr. W. G. Schauffler of Lakewood, N. J., read this paper. He said that vibratory massage, or, more properly speaking, "mechanical vibratory stimulation" was a therapeutic factor of such recent date that there had been as yet very little authoritatively written on the subject. He said that it was his purpose in this paper to give an idea of what mechanical vibratory stimulation was; what it could be used for; how to apply it; what we could expect from its use. Pressure exerted on a nerve caused it to vibrate and by an ingenious mechanism, by means of which we could at will increase or diminish the power of the stroke, we could gently stimulate a given nerve, and cause it to vibrate forcibly or even produce inhibition therein. Such a variety of conditions seemed amenable to treatment by means of vibratory massage that to enumerate them would seem like exploiting a quack "cure all." The general theory upon which this treatment was based was that all the functions and organs of the body were controlled by certain nerves and nerve centers, located principally in the spinal cord, and that, in the course of disease, if these centers are reached and treated, restoration to normal action might be expected in most cases. He had picked out six cases at random from between twenty and thirty which he had had under treatment during the past year as giving a fair idea of the variety of conditions suited for vibratory massage, and the average results obtained. Judging from his experience, vibratory massage should have a well-defined place as a most valuable aid to the general practitioner, enabling him successfully to treat a large class of cases, which he has heretofore thought it necessary to turn over to specialists or to send to sanatoria.

Progress in State Medicine and Hygiene.—Dr. Edward E. Wall of Newark, N. J., presented this paper. He first took up the subject of the "Jersey mosquito." The legislative act called the "Duffield bill" defined as a nuisance water in which mosquito larvæ were found, and it gave power to a local board of health to abate such nuisances. Last year thirty acres of the Newark meadows were ditched, the trenches were six inches wide, straight-edged, and eighteen inches deep and fifty feet apart. There was now sufficient means at their disposal to drain and clear the Newark meadows of all breeding spots for mosquitos. Monmouth Beach had been ditched to the extent of 150,000 feet and the Sandy Hook district fairly well cleared. He asked for coöperation from all parts of New Jersey and from New York in clearing Staten Island. He considered that the practicability of the scheme had been sufficiently demonstrated, and it rested with physicians to be active in matters of public welfare. Three arguments could be brought in favor of the mosquito crusade: (1) It would be worth while if it did no more than to add to our peace and comfort. (2) It materially enhanced the value of property. (3) The destruction of the Anopheles meant the destruction of malaria. He next spoke of tuberculosis.

The tubercle serum was produced and 5,000 bottles had been distributed free to Newark patients. So far 300 patients that have been treated seem to be improved. The sepsis serum was capable of far more extended use. In acute septicæmia it could be given every eight hours. We had records of a dozen cases of puerperal and post-operative sepsis in which the use of this serum as often as every two or three hours had produced results when almost every other plan had been unsuccessful. He thought the sepsis serum might be used with good results in septic scarlet fever. He said in regard to contagious diseases that during the last two or three years, New Jersey had passed through a season of smallpox, and that New Jersey was not as well educated on the subject of vaccination as Japan. There has been a marked prevalence during the past year of diphtheria, measles, German measles, and scarlet fever. With the Newark antitoxin the mortality from diphtheria was 7 per cent. as against 35 per cent. and 40 per cent. of former times. Scarlet fever was of grave import. Bacteriology had not hitherto helped us in its etiology, and we had to-day to depend on our old clinical methods. In the year 1903 there were in Newark 779 cases and 71 deaths, and in 1904, 662 cases and 60 deaths. He said that when we considered the wide range of the mortality in scarlet fever, and its multiple complications, it seemed to him that we ought to recognize the fact that the modern house was not a fit place in which to treat contagious diseases—that in large apartment houses it interfered with other families, and that in view of the necessity for a long quarantine, we should educate the public to a recognition of the fact that all these cases should be treated in fever hospitals specially constructed for the disease, where the personal danger to the patient was small and yet the general public would be protected from a great menace.

Acute Catarrhal Conjunctivitis.—Dr. Alfred Cramer of Camden, N. J., said he had been led to prepare this paper for two reasons: (1) because it was a highly contagious disease, and an exact and early diagnosis would, if proper measures were taken, both prevent its spread and minimize the dangers; and (2) because unfortunately many cases received no treatment until the usual home remedies had been tried, which almost invariably aggravated the condition. The disease was commonest in warm and changeable weather, and all ages were liable to the infection. The case books of the Howard Hospital of Philadelphia, covering a period of nine years, showed that there were 64,449 new cases treated in the Eye Dispensary, of which number 335 were diagnosed as acute catarrhal conjunctivitis, a trifle over 5 per cent. There were 175 males and 160 females. The period of incubation was thirty-six to forty-eight hours. The disease was extremely contagious. In typical cases the diagnosis was comparatively easy. With proper treatment the prognosis was favorable. The prophylactic treatment was of greatest importance and consisted of strict quarantine while there was any secretion. The treatment of the disease was simple and satisfactory Cold applications should be made to the lids during the acute stage. The eye should be kept thoroughly cleansed with boric-acid solution. Chloride of zinc, 1 gr. to the ounce, seemed to act like a specific. He strongly urged a bacteriological examination in every doubtful case of conjunctivitis. It had been estimated that 60 per cent. of the blind in the asylums of Philadelphia were blind as the result of one of the forms of conjunctivitis, often the result of carelessness or ignorance, or both.

Calomel an Intestinal Antiseptic.—Dr. Alexander McAlister of Camden, N. J., read this paper, the purpose of which was to consider the utility of antiseptics in their application to the alimentary canal and to compare the effect of calomel with those of the group of remedies commonly classed with intestinal antiseptics. The intestinal antiseptics all interfered more or less with the digestive functions. Some of the remedies were of special value, particularly the sulpho-carbolates, for controlling intestinal fetor; they were effective in minute doses. Calomel, he believed to be our best intestinal antiseptic in pediatric practice Calomel did not interfere with the action of the digestive ferments, but stimulated their functions. In the presence of free alkalies, a small portion of calomel was converted into black oxides, probably the only form in which the medicament was absorbed. Calomel liberated the stagnated bile, increased pancreatic secretions, and stimulated all the intestinal glands. At the present time one-tenth-grain doses were used more frequently than any other by the profession in general. Smaller doses would come into larger use, since the effect was better understood and the drug was applied with more skill than ever before. Whatever the condition, the first object in treatment was to impress the system by reducing abnormal bacterial activity. In gaining this point, the combination of sodium bicarbonate with calomel acted beneficially by facilitating the conversion of the insoluble chloride into soluble compounds.

The Beneficent Agency of Peritoneal Exudates, Adhesions, Aperistalsis, and Meteorism in Peritonitis.—Dr. Horace G. Wetherill of Denver, Col., said that eleven years ago he presented a paper entitled "Salpingitis and Pelvic Adhesions," when two conclusions were reached, as follows: (1) Adhesions about an inflamed tube or ovary are conservative in design and effect, and should not be disturbed till the disease back of them is removed. (2) When the disease is removed, adhesions tend to absorption and usually disappear in time. Both time and experience have served to confirm these earlier conclusions and had led to the fixed belief that certain other inevitable accompaniments of peritonitis, which had been regarded as baneful, were in reality also somewhat beneficent in their agency. Starting with certain accepted and established basic principles of modern medical science, he said it would be conceded: (1) That idiopathic peritonitis is a myth; that the disease is always either directly or indirectly of infective origin; (2) That transudation of serum, the formation of plastic exudates and adhesions, tympanites, peristaltic arrests, and muscular rigidity, were the first reactionary phases of the disease; (3) That the first effect of infective inflammation everywhere in the body was to bring about quiescence, muscular inactivity, and physiological rest in and about the parts involved; (4) That the best treatment of all inflammation was based upon promoting such an arrest of functional activity. (5) The health and life of the patient depended upon the limitation and localization of the infective process period. He asked that it be conceded that peritoneal exudations and adhesions play a very important part in protecting the patient from diffusion of infection during acute stages of the disease; could it then be questioned that our peristalsis also favored the formation of a protecting barrier? Could it be questioned, then, that meteorism, through ballooning the intestines and increasing intraabdominal impression, also served the same beneficent purpose in bringing loop to loop closely about the infecting focus and splinting the abdominal wall and diaphragm so that not even the respiratory movements should disturb the newly established quarantine station? During the pre-operating period opium was our sheet anchor in the treatment of peritonitis; it promoted peristaltic arrests and even tympanites.

Milk as an article of diet should be forbidden in all of those conditions in which peritonitis is threatening, and before and after all intraperitoneal operations. It was an ideal culture medium for the gas-forming bacteria of the intestinal tract, and he believed it to be the worst form of liquid food that could be administered, particularly in typhoid fever, gastric ulcer, appendicitis, and after abdominal operations. Opium he regarded as a valuable remedy in acute stages of peritonitis, as it relieved pain, conserved the energy of the patient, and promoted peristaltic arrest. For the

discomforts and dangers incident to extreme degrees of meteorism and antiperistalsis, he advised rectal and stomach siphons and stimulating rectal enemata. Against simple peristaltic arrest in the small intestines he believed that no remedy was necessary or justifiable.

The Agencies through Which the Infection of Typhoid Fever Is Disseminated.—Dr. W. B. Warner of Red bank, after reviewing what was known about the bacillus of Eberth and the various epidemics that had occurred in recent years, at Lowell, Mass., in 1903 in Ithaca, in Göttingen in 1900, and in his own township in 1903, he said that the methods by which typhoid-fever infection were conveyed from the sick to the well being understood, the problem of prevention was easily solved, at least theoretically, by the thorough policing of watersheds and the employment of trained and salaried dairy and general sanitary inspectors. But practically these matters required moral and financial support from the public, and these requisites the people of the present day gave grudgingly. He said that in many rural districts, and even in some towns of considerable importance where foci of infection frequently existed, the people were not only apathetic, but actually belligerent, and it thus appeared that a necessary preparatory step to an active and efficient sanitary crusade would be the education of the people.

President's Address.—Dr. Henry Mitchell of Asbury Park, N. J., said that the subject which he wished to present related to the application of modern scientific medicine, to the prevention of disease and the promotion of the public health, and, more particularly, to the relation which the State Medical Society and the members of the medical profession had held to the rise, development, and progress of public hygiene in New Jersey. At every step in this great work the members of the society were the instruments through which organized methods for defence against the spread of preventable diseases had been established, and the results, as indicated by the diminished death rates among certain preventable diseases, promised to surpass the expectations of the most enthusiastic pioneer in this field of labor.

Progress in Surgery.—Dr. Frank D. Grey of Jersey City, N. J., read this paper and referred particularly to the researches of Mikulicz, Robson, and Cammidge in pancreatic surgery and the operative conditions of the stomach by Mayo, Murphy, and Moynihan of Leeds. He said that we would soon recognize a department of Fourth of July surgery, because, according to the *Journal of the American Medical Association*, August 29, 1903, 4,449 persons were injured and 446 died, of which 406 were from tetanus caused from blank-cartridge wounds.

Progress in Bacteriology.—Dr. Joseph McFarland of Philadelphia said that comparatively few details had been added to our knowledge during the past year and no new microorganisms had been discovered. He considered the trepanosome, causing African lethargy or the sleeping sickness, and showed that its geographical distribution was the same as a certain species of fly. All trepanosomes look alike. Surra, in the Philippine Islands, was also caused by the fly and was the death of many horses. The parasite was transmitted from animal to animal by suctatorial insects. Very important work had been done by Novy and McNeil of Michigan in that they had succeeded in cultivating the trepanosomes upon ordinary culture media.

Election of Officers.—*President*, Dr. Walter B. Johnson of Paterson; *Vice-Presidents*, Drs. Henry W. Elmer of Bridgeton, Alexander Marcy, Jr., of Riverton, and Edward J. Ill of Jersey City; *Corresponding Secretary*, Dr. E. W. Hedges of Plainfield; *Recording Secretary*, Dr. William J. Chandler of South Orange; *Treasurer*, Dr. Archibald Mercer of Newark.

The next place of meeting will be Asbury Park or vicinity, June 20, 21, 22, 1905.

Cincinnati Academy of Medicine.

At a regular meeting, May 2, Dr. Wm. D. Porter presented a premature child which had been born by spontaneous craniotomy. The mother was a victim of an epithelioma of the cervix uteri, which was very hard and resistant. Dr. Porter was called in consultation and sent the woman to the hospital. A few days later he was hurriedly summoned because of a fleshy mass protruding from the vulva. On his arrival he found that the child had been born. The resistance at the cervix had caused the scalp to tear, and the brain had been protruded by the pressure of the cranial bones. The occiput was pushed up under the parietal bones, and one of these overlapped the other. The fleshy mass which had alarmed the nurse was the protruded brain.

Dr. Robt. Carothers read a paper on "Ununited Fractures." He said in brief: "If after fracture a bone is still ununited after six to eight weeks, the condition is called delayed union, and if the condition has persisted for three to four months it is spoken of as ununited fracture; but cases have been reported in which bony union has occurred after eighteen months without surgical intervention. Stimson gives the frequency of ununited fracture at one in 352 cases, the humerus, tibia and femur being most frequently the site. The patella, olecranon, neck of femur, and ribs are not considered, as bony union is the exception in these cases. The callus which forms may be normal in amount, but instead of becoming ossified it remains soft, or is converted into fibrous tissue. The condition most often results after faulty immobilization. In some cases there is the formation of an actual false joint, and in others no attempt is made at union and the ends of the bone atrophy. Most interesting are the causes and treatment. The causes given by Gurlt and Norris are constitutional and local. The first are syphilis, anæmia, drains on the system, as pregnancy and lactation, wasting diseases, as typhoid and malaria, alcoholism, paralysis, scurvy, gout, rickets, osteomalacia, and old age. These authors do not mention tuberculosis and report many more cases in which union has occurred in the presence of these diseases than cases of non-union attributed to them. The local causes are defective reduction and immobilization, too light bandaging, which interferes with the blood supply, too long application of cold to the part, injury to the main artery of the limb or of the nutrient artery of the bone, defective innervation due to damage to trophic nerves or nerve centers, disease at seat of fracture, as tumors, syphilis, or tuberculosis. When two parallel bones are fractured, and one unites quickly, it may prevent union of the other by interfering with acurate opposition and preventing the irritation of the contracting muscles. One of the most frequent causes is the interposition of soft parts between the fragments. The skiagraph is of value in determining the relation of the fragments, and when, after six to eight weeks, these are in good position one is justified in waiting, but when this method shows the opposition to be poor much valuable time can be saved by operation. Unfortunately the interposition of soft parts does not show in the skiagraph. All possible constitutional causes should be treated and the patient's general health improved by good food, fresh air, and sunshine. Phosphate of lime and thyroid extract have also given good results. Massage and bandages, applied tightly above the fracture for two to three hours on three to four consecutive days, act by increasing the congestion of the part. The local injection of irritants is dangerous. In the case of the lower extremity an ambulatory dressing is often successful. Under anæsthesia the fragments can be rubbed together to set up irritation, or the ends of the bone can be drilled through the skin, or an electrode passed between them. When palliative measures fail operation must be done. The time for operation is very variable,

about four months being the most usual time; but this must be decided for each individual case. Operative work must be aseptic and the incision made in the part where the fewest important structures are found. The bone should be disturbed as little as possible, the ends freshened and brought together, being secured by suture; the best is forty-day chromicized catgut. The bones should be drilled on the slant so as to come out in the medullary cavity, the periosteum being raised and the sutures not drawn too tight. McCurdy brings the long ends of his sutures out through the wound and secures them to a solid splint, thus holding the fragments. When the ends are atrophied they can sometimes be secured by drilling and inserting an ivory plug, but at times the ends must be resected and the gap filled by shortening the bone, or by the use of fresh or decalcified bone or powdered decalcified bone. When the fragments are held apart by a parallel bone the gap can be filled by decalcified bone, or the second bone can be broken. Medullary plugs and ferules are to be avoided unless other methods fail, because they so frequently demand removal."

Books Received.

While the MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending July 23, 1904:

	Cases.	Deaths.
Measles	201	7
Diphtheria and croup	275	25
Scarlet fever	88	3
Smallpox	2	...
Varicella	20	1
Tuberculosis	299	168
Typhoid fever	65	13
Cerebrospinal meningitis	...	22

The Japanese Red Cross Nursing Association.—The *Japan Mail* describes the organization and objects of this association as follows: The president of the association is H.I.H. Princess Komatsu, the members are all ladies, and the manager is Marchioness Nabeshima. All the members are trained in the duties of the nurse, and their work is consequently of the greatest assistance to the Red Cross Society. Bandages and many other surgical necessities are sent to the field by the association. Its members visit the wounded men in the hospitals and also work as nurses there. Some of them even go to the front. They also keep in close touch with the regular nurses of the Red Cross, seeing them off when they start for the field, welcoming them when they return, sending presents and comforts to them during the discharge of their arduous functions and seeking otherwise to encourage and assist them. It will thus be seen that the work done by the association is wide and very helpful. Though its operations are, so to speak, subordinate to the larger work of the Red Cross, it usefully supplements the latter, and is also entirely self-supporting.

The Relation of Certain Extracranial and Intracranial Hemorrhages in the Newborn.—J. Howell Evans has sought some common factor which may act whether the molding of the head at birth take place from the superior cephalic planes or from the inferior cephalic planes. Only those hemorrhages connected with the parietal bone are considered here. The parietal bone is generally developed from one center, whence radiating osteogenetic fibers pass toward the borders of the bone. If this bone become developed from two ossific centers, then the radiating osteogenetic fibers pass to the borders of the bone, and at the points furthest from the centers tend to leave gaps. Such a gap exists for a long time in the region of the parietal fontanelle, forming a membranous space, which usually becomes closed about the fourth month of intrauterine life. A trace of it may persist throughout life as the parietal foramen, serving for the transmission of certain vessels. The importance of parietal foramina and their transmitted vessels in the production of these various pathological hemorrhages has scarcely been entertained. Transmitted through the parietal foramen, intraparietal suture, or sagittal fontanelle, are blood-vessels—an artery and a vein—which form one of those important channels of vascular communication between the structures which lie without and those which lie within the skull. In a normal fetal skull these vessels are safe from injury. But with accessory sutures and irregular molding, they are liable to mechanical injury. This injury may lead to rupture of the artery (*a*) on the outer side of skull; (*b*) on the inner side of skull, tearing of the vein; laceration of both vessels; thrombosis of these vessels. Such an injury may occur on both sides, but is more liable to occur in connection with the parietal bone which lies outermost. To these forms of injury all vertical hemorrhages of the reactionary period of the newborn can be traced.—*The British Journal of Children's Diseases.*

RECTAL CONSTIPATION IN WOMEN.*

By GRACE PECKHAM MURRAY, M.D.,

MEMBER OF THE NEW YORK STATE MEDICAL SOCIETY, THE ACADEMY OF MEDICINE, THE NEW YORK COUNTY MEDICAL SOCIETY, THE NEW YORK NEUROLOGICAL SOCIETY, THE WOMEN'S MEDICAL ASSOCIATION; PROFESSOR ADJUNCT IN WOMEN'S DISEASES, NEW YORK POST-GRADUATE SCHOOL AND HOSPITAL, ETC., ETC.

THE subject of constipation in general, while one of the greatest importance in the human economy, is the least understood and given the least study. It is a question which involves the understanding of diet; of occupation; of chemistry as well as the whole process of assimilation; of the mechanical obstructions and inflammatory conditions of the intestinal canal and adjacent structures, and, moreover, the nervous reflex and psychical influences, which are more easily recognized in this part of the human system than anywhere else. The amount of waste which should be thrown off by the individual in the twenty-four hours, and the disposal of it are vital topics, which a practitioner should thoroughly understand and direct in order to obtain satisfactory results.

The physician who rightly determines and administers the various medicines embraced by the term cathartics is a genius in his materia medica. He must know when the vegetable compounds are best, when to give salines, and whether in the concrete form of powders or held in solution in the many spring waters to which a newly discovered one is added daily, and when not to pass by the oils which held such a prominent position in the olden time.

Leaving all these general questions, I will devote myself to a very small part of the subject and one which is not so generally recognized even as these others, namely, to some forms of rectal constipation in women, which may be understood by a few rectal specialists and gynecologists. All physicians in a general way are cognizant of the prevalence of constipation in women. Scarcely a monograph or textbook on the subject fails to point out the fact. Owing to the greater inactivity of women, their mode of life and manner of occupations, making them much more sedentary than men, few there are who do not suffer from constipation. So general is this that I am always surprised when a patient does not claim to be constipated.

Rectal constipation in women is mostly of mechanical origin. Some years ago Dr. Goodell of Philadelphia called attention to a form of constipation due to nervous disturbances of the rectum. At the time it raised the discussion whether such a condition of purely nervous origin could exist, and it was thought by some that what appeared to be a nervous rectum was not such in reality, but was due to some undiscovered disturbance. A purely rectal neurosis may exist without doubt. The psychical effect of emotions is readily recognized. Defecation may be easily interfered with, if haste is considered or modesty is shocked. One writer has recommended, as a preventive of constipation, that the mind assist the act, but as, in a measure, the movement of the bowels is reflex, I have known women who have been much more successful at stool by occupying their thoughts in other ways, such as reading or looking at pictures.

The mechanical causes which are peculiar to women are those of uterine displacement, prolapsus of that organ and the vaginal walls, especially rectocele and neoplasms, the most frequent of which are the myomata. The forward displacement of the uterus seldom gives rise to much trouble, unless it be a version in which the uterus lies transversely across the pelvis, so that the cervix pointing backward impinges on the rectovaginal wall. In which case it may prove as much of an obstruction as the reflexed body itself. This is not a usual condition, but occasionally I have encountered it. The backward displacements, especially the flexions, are what occasion the greatest rectal interference from that organ. This is especially true when the flexion is in the upper third of the body, and also when the organ is enlarged from a metritis. The intimate relation of the rectum to the uterus, and the ovaries, which lie almost against one another at the left sacroiliac synchondrosis is the cause of the trouble, which may be found on one side or the other. Habitual constipation may press on ovaries and render them sensitive and inflamed. The pressure on the blood-vessels from masses of fæces promote disturbances in the circulation, which in turn may lead to inflammatory conditions and displacements. The rectum, however, is not so often the offender with its contents as one has been led to suppose. But the pressure of a heavy retroflexed uterus will in nine cases out of ten produce hemorrhoids by its interference with the rectal circulation, and will prevent the proper evacuation of the bowels. The accommodation of the rectum to such displacements and the presence of fibroids is a matter of marvel in many instances. I have known of cases of retroflexion, however, which so far obstructed the mass of fæces that the movements have been small and tape-like, such as are seen in true constriction of the rectum itself.

These conditions which have just been described have been fully recognized, but that which has caused me to present this paper, while referred to in a general way, has not been given the attention that it should have, because of its prevalence as a condition of rectal constipation in women, namely, that which comes from the pouching of the rectum, bringing down the rectovaginal wall. Rectocele has often been mentioned among the causes of constipation, but its importance and mechanism have been overlooked. Later writers have advanced the theory that the rectum remains empty except at the time the bowels should move, and that the sigmoid flexure acts as a receptacle for the fæces in the meantime. Judging from the many women that I have examined, I have little doubt that this is the case. Whether the bowels are emptied by a siphoning process, as has been suggested, which arouses the peristaltic action, or by peristaltic action alone, I

*Read before the Section of Gynecology, New York Academy of Medicine, June 2, 1904.

cannot say, but I believe that if the mass is not discharged, that an antiperistaltic action takes place and the mass is drawn back from the rectum. The wedge-shaped perineal body separates the anus from the vulva and acts as a guide to the fæces, directing the mass toward the anus, this portion of the rectal canal making an angle with its apex toward the vagina. As a result of difficult defecation and straining at stool, the fecal mass presses downward upon the apex of the perineal body, and little by little the pouch is formed, pressing the perineal body to one side that is backward, and as year after year passes and the act of defecation becomes more difficult, this pouch descends to the floor of the perineum. The direction of pressure has changed and the emptying of the rectum becomes a matter of great trouble, and even if this is accomplished generally there will remain behind masses which will give rise to further trouble. In confirmation of the ease with which the rectum prolapses from lack of perineal support are the experiments of Lenormalt, who asserts that "The rectum is above all held in its position by its perineal connections, muscular and aponeurotic, much more than by its peritoneum and mesenteric connections."

In order to understand more fully the rectal

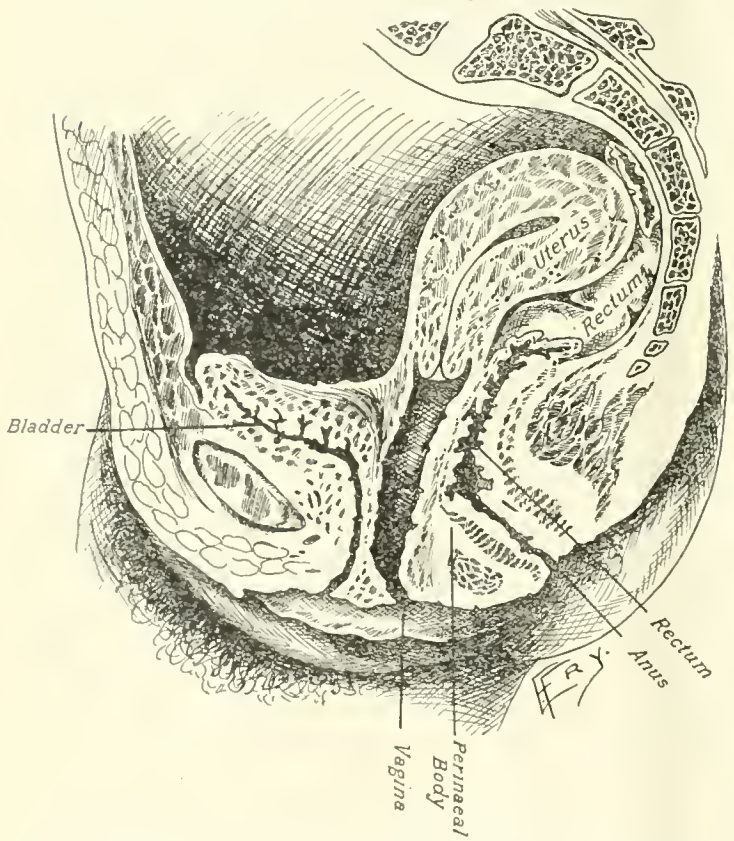

FIG. 1. Section showing the normal relations of the rectum to the vagina and perineal body; it shows also the pressure exerted by a retroflexed uterus on the rectum.*

*In figures 1 and 3 the relation of rectum and vagina, as well as the other organs of the pelvis, are those which are given in the Sellheim's "Topographischer Atlas zur normalen und pathologischen Anatomie des weiblichen Beckens." In making the sections from which the drawings of this altas were taken every precaution was observed to keep the organs and tissues in the same relations as in life. The pelvis was removed from the cadaver, from ten to fourteen hours after death, and placed in large tanks in a 4 to 5 per cent. formaldehyde solution for four to six weeks, afterward hardened in a solution of alcohol of constantly increasing strength, then soaked in alcohol-ether, impregnated with a thin celluloid solution and finally with a thicker celluloid solution. After remaining several days in 70 to 80 per cent. alcohol, the pelvis was ready for section.

constipation of women, the matter of intraabdominal pressure should come under consideration. When writing the monograph on Complete Pro-

FIG. 2. Dissection showing the bulging of the posterior wall of the vagina caused by rectal retention of fæces.

cidentia, as well as since, I was convinced that this subject of intraabdominal pressure is one of great importance in the consideration of uterine disease, and is much more a matter of individual idiosyncrasy, than one would suppose, and its direction will occasion prolapse under circumstances which might not obtain if this same pressure were different. That one must look to this to account for the cases of complete procidentia uteri in the unmarried and in the nullipara. A similar, but reverse condition obtains in these cases of rectocele occasioned by constipation, for it can be readily seen from the nature of the case that the intraabdominal pressure for the rectum would be at right angles to that for the vagina for, as Hart demonstrates, it acts so as to press the anterior and posterior walls together in order to expel the contents. When the rectum is displaced and brought down with the vaginal wall, the pressure is changed to that of the vagina, and instead of the mass being propelled toward the anal orifice, it takes the trend of the vagina and brings down the pouch more and more, and when, owing to the perineal attachments, it can descend no farther it becomes enlarged by the thinning of the walls of the sac. In almost all the sections of the pelvis which are given to illustrate the relation of vagina to the rectum they are wrongly drawn. One would suppose the orifice of the vulva was on the same line as the anus or above it. Such is not the case. The opening of the vagina at the vulva is in most cases fully an inch lower than the anus, and this is where the pouch is formed.

In the emptying of the bowels, unless the sac is pushed up from below, there will remain masses of fæces, the size depending upon the depth and size, of the sac. These masses become sciballous and give rise to trouble. In the first place they may act as foreign bodies and cause rectal catarrh and irritation. But the greatest disturbance is due to the absorption of their toxic properties into the system. It does not take long, as I have often proven by examination, for the fæces to become hard and dry after remaining in the rectum. A

few hours are all that are required, for what was soft and moist in the morning has lost much of its bulk and has become hard by afternoon. It is generally acknowledged by investigators that there has been an absorption through the rectal walls and that the system has taken these poisons back, which once it had eliminated, and has sent them through the circulation again that they poison the blood and wreak their effects upon the bodily structures. There is no doubt that this is the case. Constitutional symptoms, from incomplete elimination of effete matters, are marked. Bouchard distinctly announces that his studies show that fecal matter is toxic. Passing by what he says of fermentation and the effects of acidity in causing gases, diarrhœa, and vomiting, we come to the other phenomena, which have long been recognized as the symptoms accompanying constipation, such as fatigue, depression, headache, buzzing in the ears, deafness, disturbance of the sight, and vertigo. The skin, too, becomes rough and sallow. The subject of autointoxication is in its infancy, but, as investigation proceeds, the facts point more and more conclusively, that in so far as elimination of the effete productions of the body is defective,, by so much is impaired the bodily equilibrium.

In regard to treatment, it will be seen how

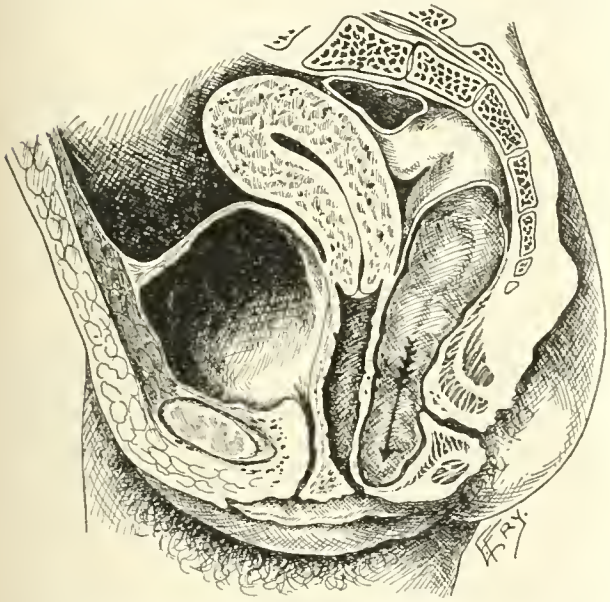

Fig. 3. Section showing the pouching effect of an accumulation of fæces in the rectum, forcing down the rectovaginal wall.

little is the value of the various cathartics in remedying the rectal constipation of women, since the trouble is due in the great majority of cases to mechanical causes. It goes without saying that the displacements should be corrected, but in those cases in which this is not possible, at least immediately, or when there are neoplasms which cannot be operated upon, it is necessary to give laxatives to soften the fæces that they may pass the obstruction more easily, and also, that in passing they may press less upon the ovaries, blood-vessels, and tubes. There exists also atonic states of the rectum, in which a laxative acts favorably, and prevents the straining and difficult defecation which will produce the condition of rectocele that has been described. The preparations of have been found by everyone to be the best and longest borne of the vegetable cathartics. Two parts of cascara, the fluid extract of cascara to one of glycerin, to which is added the spirit of anise, has been found most useful in cases of chronic constipation, given a teaspoonful in water before each meal. This will unload the bowels, after which the amount is reduced to half a teaspoonful or even a few drops, taking it in a third of a glass of water before each meal instead of a larger dose at night. It acts in general constipation to give complete relief. The belladonna, strychnine, and aloin pills are also useful. In cases with a gouty, rheumatic, or neuralgic tendency, some one of the salines or mineral waters are better.

The uselessness of cathartics in those patients who have the pouched rectum, formed by the pulling down of the rectovaginal wall, will be at once patent. In fact, the softer the fæces, the more

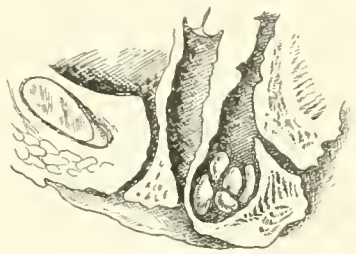

Fig. 4. Section showing retention of fecal masses in the rectal pouch.

easily they become packed. The anal orifice in these cases is liable to become contracted, which forms another obstacle to the passing of the stool. Stretching the rectum by means of rectal plugs or bougies is therefore useful. Such procedures have a tendency to obliterate the sac. Patients should be instructed not to strain at stool until the sphincters are relaxed and the bowel has begun to empty itself. The use of the enema is to be reprehended, that is as usually taken. Women frequently form the habit, and many a case of rectal constipation can date its commencement with the beginning of that practice. The sensibility of the sphincter is

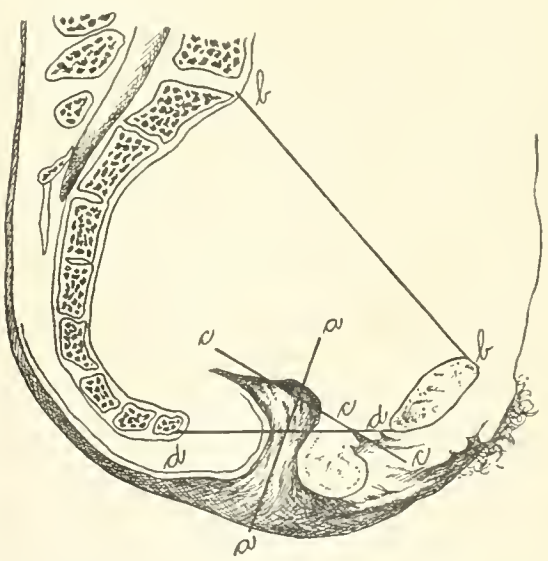

Fig. 5. Diagram showing the direction of intraabdominal pressure (Hart); *a,a*, anal axis; *b,b*, conjugate of the brim; *c,c*, vaginal axis, at right agles to *a,a*,; *d,d*, plane of the horizon.

dulled and it will soon cease to respond, except to artificial stimulation. Suppositories are useful in that they soften the contents of the bowel and relax the sphincters. Glycerin suppositories are good for this purpose, although there are women now and then who are irritated by their application, just as there are those who cannot use glycerin as a topical application in other parts of the body. For such the gluten suppositories may avail. In many cases great benefit has been obtained by the use of olive-oil injections as recommended by Kussmaul and Fleiner, and further advocated by

Dr. Max Einhorn. The patient, upon retiring, injects into the rectum the amount of olive oil which she can easily retain during the night. The amount varies greatly with different individuals and with practice—one can usually begin with half a cupful and after a little can retain two-thirds or even one cupful. The oil is very soothing to the rectum and allays the irritation which has been occasioned by retained fæces. It is especially beneficial to those who are thin. I have seen in such an appreciable gain in weight. The directions are to take the injections nightly for three weeks and then every other night for three weeks, and then less often, gradually discontinuing them as one is able.

REMARKS AND SUMMARY.

1. It is generally recognized that women for various reasons are most subject to constipation, nevertheless rectal constipation, from which a large number suffer, has received, at the hands of the profession, scant consideration.

2. Rectal constipation may be, but is rarely, due to a nervous condition, *i.e.* nervous rectum. While it may occur as the result of inflammatory conditions, such as hemorrhoids, fistulæ, and fissures, which are common to men and women alike, in very many cases it is occasioned because of the peculiar anatomical construction of the parts, and is mechanical in its origin. Anteversions, retrodisplacements, neoplasms, especially fibroids, and periuterine inflammations obstruct the downward passage of the fæces. Conversely owing to the close juxtaposition of the rectum and the genital organs of the woman, a loaded rectum in its turn may occasion ovarian and uterine displacements and disorders.

3. A form of rectal constipation which heretofore has received but little recognition is that which occasions and is the result of the pulling down of the rectovaginal septum, thereby forming a pouch, constantly increasing in size, changing the direction of the intraabdominal rectal pressure to that of the vaginal, which is at right angles to it, and making it difficult for the rectal sphincters to relax so as to void the contents of the bowel. The result is not only to render defecation difficult but incomplete. The retention of fecal matter causes rectal irritation and autointoxication. This condition occurs not only in women who have borne children, but in nullipara and the unmarried, although not so frequently in the latter.

4. In regard to treatment: Cathartics may be useful in those cases in which the obstruction is due to inflamed and displaced organs or neoplasms, which prevent the descent of the contents of the bowel and in which the hardened masses of the fæces press and inflame the genital organs, but would be useless in those cases in which there has been a displacement of the rectovaginal wall. In such cases, glycerin or gluten suppositories, or injections of small amounts of olive oil, glycerin, or soothing fluids, may be employed. The use of daily enemata, as ordinarily practised, is to be reprehended from every point of view. The use of bougies or dilators may prove beneficial. For constipation of purely rectal origin, massage, electricity, and measures designed to improve peristaltic action are of no avail.

HYPODERMIC INJECTION OF STRYCHNINE NITRATE IN THE TREATMENT OF PROGRESSIVE MUSCULAR ATROPHY.

BY SANGER BROWN, M.D.,
CHICAGO.

SOON after the publication of the new edition of "Quain's Dictionary of Medicine" in 1895, I was surprised to notice in the article on progressive muscular atrophy, by Sir William Gowers of London, how hopefully he expressed himself regarding the value of strychnine nitrate given hypodermically in the treatment of that disease. My surprise was the greater because he had previously stated in his textbook on "Diseases of the Nervous System" the commonly accepted view that the malady lay without the range of therapeutics.

I do not know to whom belongs the credit of originating this method and first asserting or demonstrating its value, but since it came to my notice I have embraced every opportunity of using it, and while my results have not been so happy as Professor Gowers' statements in the article above referred to might have prepared me to expect—and in the last edition of his textbook above mentioned, he has modified his formerly expressed views somewhat—they have nevertheless been highly satisfactory in some instances, and prompt me to publish the clinical notes given below. Furthermore, I might add, judging from conversation with my confrères and the perusal of current medical literature, this measure of treatment has not received anything like the attention it deserves.

For an adult the dose should be $\frac{1}{25}$ of a grain once daily for six weeks, resumed after an intermission of two weeks, and so on until several courses have been taken. Though many patients can bear a larger dose than this without exhibiting unpleasant symptoms, I have had better results when I did not yield to the impulse sometimes experienced, to administer a larger quantity. Possibly a cer-

tain amount of the drug might act as a tonic and restorative to the degenerating neurons, while more might accelerate the process of decay.

It appears that no other form of strychnine than the nitrate given hypodermatically, and no form whatever, not even the nitrate itself, given by the mouth, can influence the course of the disease favorably. That the nitrate is a comparatively volatile substance, and that it is not exposed to the action of the digestive secretions is somewhat suggestive of a possible specific incidence when given subcutaneously.

Apart from the muscular dystrophies, different authors have separated progressive muscular atrophy into types according to (1) age; (2) distribution of the atrophied muscles; (3) condition of affected muscles as to tonicity, and (4) supposed nature of the pathological process affecting the neurons concerned; consequently in the literature are found such terms as (*a*) juvenile type, (*b*) progressive bulbar paralysis, scapulohumeral type, (*c*) amyotrophic lateral sclerosis (tonic or spastic type), and (*d*) chronic anterior poliomyelitis.

The propriety of such divisions cannot be discussed here. They are certainly not yet founded upon a firmly established pathological basis. Inasmuch, however, as they all present positive evidence of muscular wasting, due to destructive changes in the peripheral motor neurons, no principle of medical nomenclature is violated by, for the present, at least, employing the term progressive muscular atrophy as properly applicable to them all.

Viewed from this general point, there are wide variations in symptoms, but, so far, my rather limited experience with the treatment herein described does not prompt me to attempt to group cases with reference to their curability, though it would not seem unreasonable to expect that future research might furnish data from which such calculations could be made. Again, it would appear that the variable nature of the pathological process going on in the neuron body, as inferred from the progress of the symptoms in different cases, suggest a variation in the dosage. That is to say, in a rapidly progressive case, in which the destructive (degenerative or, perhaps, even inflammatory) process was comparatively active, strychnine given to the extent of causing twitching or hypertonicity in healthy muscles by its effect on their respective nourons would almost certainly add fuel to the flame, albeit just here the practitioner might feel impelled to push his remedy. Moreover, in these rapidly advancing cases my success has been least, and it does not now seem to me improbable that a much smaller dose than I gave would better have been employed, if, indeed, any degree whatsoever of this sort of medication could have been beneficial.

Case I.—Referred to me during the summer of 1896 by Dr. T. M. Hardie, whom he had consulted for hoarseness. Man of twenty-five years, single, salesman in millinery store. Correct habits. nothing significant in personal or family history. Three or four months before began to suffer from hoarseness, which had steadily increased, and for about the same length of time his left arm had grown progressively weaker, especially noticeable when he had occasion to raise a package to a shelf above his head. Had suffered no pain or paræsthesia, and though his appetite had not been as strong as it ought to be, he had regarded his general health as fairly satisfactory. Examination showed no sensory changes; superficial and deep reflexes normal, and nothing in the viscera or elsewhere demanding comment. The left vocal cord was paralyzed (Dr. T. Melville Hardie). The presence of the left sternocleidomastoid could not be demonstrated, either by inspection or palpation—electrical tests were not made; the upper border of the left trapezious was much wasted, as shown by comparing the contour of the two sides of the neck. The patient was taught the use of the hypodermic syringe and sent home (several hundred miles from Chicago). He was directed to inject strychnine nitrate, grains $\frac{1}{30}$ once a day for six weeks, discontinue two weeks, and then resume six weeks more. I heard nothing further from him till March, 1900, when he unexpectedly called to report, saying it was his first visit to Chicago since he had left it to begin treatment. The muscles previously atrophied appeared to be entirely restored. The patient stated that his malady did not progress after the second week, and by the fourth week he had certainly began to improve. At the end of three months he regarded himself as cured, and permanently discontinued treatment. In the meantime there had been some improvement in appetite and general vigor.

Case II.—September, 1896. Gentlewoman of twenty-one years, single, habits correct; nothing of moment in personal or family history. About three months before first noticed weakness of right hand, especially in buttoning clothing (a defect commonly cited when the disease begins in the hands); soon after, some flattening of the thenar eminence. Slight paræsthesia about the radial side of hand occurred early, but patient could not be certain if it preceded or followed the commencement of weakness. The atrophy had steadily advanced and extended to the interosseous spaces and also to the muscles of the forearm. Twitching in the wasting muscles had also been noticed. Three or four weeks before I saw her, the disease had made its appearance in the left hand and followed a similar course to that described in reference to the right. The muscles affected were flaccid and no hypertonicity was apparent anywhere, except that the knee-jerks were much increased, and there was ankle clonus. I may say here, parenthetically, that this condition of the lower extremities has been accounted for in similar cases and supported by anatomical findings, too, by supposing such a lateral extension of the pathological process in the cervical cord as to involve the crossed pyramidal tracts. There was no pain or tenderness, and sensation was not impaired even in the parts where slight paræsthesia existed. The general health was satisfactory, and a careful examination revealed nothing demanding comment beyond the condition of the wasted muscles. In them flickering was frequent and pronounced, and degeneration reaction was easily demonstrated.

Though not living in the city, the family physician was present at the examination, and the same treatment was advised as in Case I. Ultimately, through involvement of respiratory centers in the medulla, and without any material arrest in the march of the symptoms, a fatal result was reached in about two years. But the treatment was not carried out according to directions, as the physician afterward informed me. Improvement not appearing as promptly as he had hoped, he soon began to increase the dose and carried it to such point that for several months he gave her "all she could stand," even $\frac{1}{5}$ of a grain twice a day.

Case III.—June, 1889. Sister of Charity, aged forty-one years; a few months before noticed marked paræsthesia about radial side of hand, involving the thumb and index-finger. Somewhat

later weakness and wasting appeared in the thenar muscles and index-finger, the latter growing small and pointed, as she expressed it. A few weeks before I saw her paræsthesia made its appearance in the left hand, as it had previously done in the right, followed by weakness and wasting. The patient was in good general health, and had been so throughout. In the hand first effected, perceptible wasting had not extended beyond the thenar muscles and those of the index-finger, and in the other only the muscles of the thumb were visibly involved; and these, though distinctly, not greatly so. Degeneration reaction could be demonstrated in the thenar muscles of the right hand; the superficial and deep reflexes were normal. I saw this case repeatedly at intervals varying from a few weeks to two months for over two years, when the patient was assigned to duty in a distant State. There appeared to be an element of hysteria in the sensory symptoms, inasmuch as while the paræsthesia lasted the area involved by it presented variations in the reaction to touch and pin-pricks between distinct reduction and normal. The treatment was carefully carried out. Three six weeks' courses with intervals of two weeks were given at the outset, and afterward three six weeks' courses at irregular intervals, because the patient fancied she felt a slight return of the paræsthesia. One-twenty-fifth of a grain of strychnine nitrate was used throughout. Distinct improvement was noticed after the first few weeks and continued for several months until no atrophy or weakness was discernible in the hand last affected, and the other had grown much stronger, with considerable restitution of the wasted muscles. With the exception of an occasional suggestion of a slight return of the paræsthesia, which may have been hysterical, and due to over-anxiety on the part of the patient, there has been no return of the symptoms.

Case IV.—In October, 1900, there came to my clinic, at the Post-Graduate School, a carriage painter, thirty-four years of age, married and intemperate. He was a well-nourished man, and said his general health had been good, except that during the past seven or eight years he had suffered from several attacks of painters' colic, and during about the same period had also, on several occasions, been afflicted with lead palsy or wrist-drop. He had always made good recoveries from both conditions under treatment, except that for the last two or three years extension in the wrists had not been quite as strong as formerly. About ten months ago the wrists began to grow weaker, more slowly than in previous attacks, and, in addition to this, the thumbs became very weak, especially the right, so he could no longer hold his brush well. Progressive wasting was now noticed, first in the thenar muscles, then in the interossei, and, lastly, in the muscles of the forearms. In the right hand the disease was a month or two in advance of the left from the first, *i.e.* in this present instance, while in previous attacks they had been affected about equally and simultaneously. At no time had there been any pain, paræsthesia, or anæsthesia. Examination showed nothing worthy of comment outside of the wasted muscles. Sensation was perfect, and the reflexes were not materially altered, except, of course, in the atrophied muscles, which were flaccid. The hands were practically useless, and the wasting of their muscles extreme. The metacarpal bone of the thumb was in a plane with that of the fingers. Improvement under treatment as specified in the other cases was prompt and pronounced. It was continued for about ten weeks, inclusive of the usual two weeks' interval, the patient coming daily to the clinic. Toward the end of this time, however, he so frequently presented himself in a drunk and disorderly condition that his further attendance was discouraged, and he was lost sight of, after having regained considerable use of the hands.

While, as previously stated, this method of treatment has, in my hands, fallen short of the expectations I had formed of it, nevertheless it has gone a long way to dissipate the horrible sense of depression, discouragement, or even despair, which the prognostic contemplation of these cases hitherto aroused.

In conclusion, it should be added that the value of hygienic measures, and the judicious use of electricity, massage, and gymnastics, always recognized as of great importance, is rather enhanced than otherwise, when used in conjunction with the strychnine treatment herein advocated.

100 State Street.

THE CLINICAL FEATURES OF THE EPIDEMIC OF DYSENTERY AT TUCKAHOE, N. Y., DURING THE SUMMER OF 1902.*

By OLIVER L. AUSTIN, M.D.,
TUCKAHOE, N. Y.

The purpose of this paper is to describe some of the clinical features of an epidemic of dysentery which prevailed in Tuckahoe and its environs in the summer of 1902. Life-long residents of the place have told me that about eighteen years ago a similar outbreak of the disease occurred. Since that time dysentery has been neither endemic nor markedly sporadic. During the last five and one-half years I had not seen an unmistakable case of the malady in this place, where summer diarrhœas are very prevalent, until early July brought the first case of the epidemic. This patient was an infant living across the Yonkers line, about a mile and one-half from the center of the village of Tuckahoe. Within a few days new cases appeared in widely separated localities from one end of this section to the other. During July the epidemic increased, reaching its height the last of August, diminishing rapidly during September, with a few new cases observed early in October. During this period I treated 234 cases, of which I have retained complete histories, and I saw others of which I have no record. It is from the histories of these recorded cases that the facts for this paper are obtained.

The origin of the epidemic has not been discovered. So widely scattered were the first cases in families having no relation of any sort, one with another, that only one wide-reaching source of infection could have begun and maintained the outbreak.

The water supply was suspected first. None of the earliest cases occurred in the watershed of the town supply, nor did a careful search reveal a preceding, unrecognized case which could have infected the reservoir or its tributaries. Of the first 20 cases I saw, only 8 used town water exclusively; 5, a few times during the preceding month, had drunk the water, while 7 had used none but well or spring water during that interval. Of all infected families, less than one-half consumed town water habitually.

My first case was in the family of a milkman of most uncleanly habits, yet the succeeding thirty-four cases were in families not supplied with milk by this dealer; in fact, less than 5 per cent. of all the cases were in households furnished milk by this man. Nine different dealers, supplied the infected house-

*Read before the Jenkins Medical Association.

holds. Three infants had been exclusively breast-fed by cleanly and uninfected mothers.

While in all probability the Shiga bacillus, which appeared to cause the disease, entered the system by way of the mouth, it was not determined that any one article of food or drink was the usual medium. In two families the utmost precaution was exercised in vain, even before a number had become infected, the people going so far as to use no uncooked food, no unboiled drink, carefully washing the table service and bathing the hands immediately before eating.

Cases occurred in families of all classes, yet about four times more often in the insanitary homes of the poor; and it was observed that there would be but one case, or at the most two, in a well-governed family, while several cases would be the rule in a filthy household. Uncleanliness undoubtedly increased the number of cases, but it seemed to exert no influence on the severity of an individual case. Four of the eight worst cases I saw were in homes where cleanliness and hygiene were practised as cardinal virtues. The severity of the cases did not vary with the locality nor with the date of occurrence, nor were the later cases in a family more severe than the earlier ones. While the mortality was highest for infants, this was the result, probably, of their small power of resistance. Very severe and prolonged cases were seen in robust adults.

Thirty-one per cent. of all cases were infants under three years, yet no age was exempt. Five cases were men and two were women over seventy. The disease did not appear to select for victims those of diminished vitality, for less than 10 per cent. of the infants had inherited tainted constitutions, or had been enfeebled by preceding sickness, and in only 2 per cent. of the remaining cases was there preceding enfeeblement. Eleven patients were men of unusual health and vigor. In one family, consisting of an aged woman, 3 other adults and 3 children, every member had the disease; 2 cases being severe, 3 of moderate severity, and 2 mild.

Before describing in detail the several symptoms of the disease, it may be well to present the composite picture of a number of typical cases of medium severity.

Without prodromal symptoms, a diarrhœa begins with movements every two hours. This is accompanied by some abdominal pain of a colicky character and decided prostration. Within a few hours the stools become more frequent and are mixed with mucus and bright blood. The temperature rises to 101°, with an increase in the pulse rate to 120. There is moderate vomiting and some headache. The abdominal pain increases, becomes located over some part of the colon, and is constant with exacerbations. Accompanying this is a beginning tenesmus. At the end of forty-eight hours the disease is at its height. There is a constant desire to stool and a severe tenesmus which give the patient no rest. At intervals of a few minutes there are small stools consisting of a little watery, fecal matter, considerable tarry and bright blood, and some thick, stringy mucus. After three or four stools, there is a remission for an hour or two, then again a number of movements in rapid succession. The abdominal pain has become very severe and gives the patient no respite. The vomiting has checked somewhat, thirst is excessive, and there is complete anorexia. The temperature remains the same, but the pulse becomes more rapid and of poorer quality. The most prominent symptom is the great prostration, out of all proportion to the others.

This condition prevails for about ten days, the only changes being a rapid increase of the prostration and emaciation, lessened tendency to vomiting, less tenesmus, longer rests between the series of stools. Then begins a gradual amelioration of the symptoms protracted over a period of ten days. The movements are less frequent and contain less blood and more mucus. The tenesmus and abdominal pain disappear rapidly. Thirst is less urgent. The appetite returns and the craving for food becomes great. The temperature has reached normal, but the pulse remains rapid. Convalescence is slow, the presence of mucus in the dejecta and the tenderness to pressure over the colon being the last symptoms to disappear. With care, recovery is accomplished and the patient is about at the end of four weeks, but emaciation, anæmia, and lack of strength remain much longer.

Diarrhœa with blood in the stools is essential to a diagnosis of dysentery, and was present in every case I saw, yet the several characteristics of this symptom varied greatly. In 85 per cent. of the cases diarrhœa was the first symptom; in 91 per cent. it had started during the first twelve hours, in 98 per cent. it was observed within eighteen hours, while in only three cases it was developed as late as thirty-six hours from the onset of vomiting, pain, and temperature. In about 75 per cent. of the cases its duration was that of the other symptoms. The longest instance of continued diarrhœa, not the result of a relapse, was from July 23 to September 2, in a child named Everitt.

The number of stools varied greatly in the different cases and in the same individual at different times. As few as 3 stools and as many as 63 a day were noted. Eight was the average for the first day, 18 for the next five or seven days, and 3 or 4 a day thereafter in cases responding well to treatment.

At the outset, the dejecta were of moderate size, soft, and green or yellow, in color. Soon they lessened in size and were more fluid, to become rapidly the characteristic small stool of about an ounce, consisting of a little watery, green fecal matter, mixed with a variable amount of bright or tarry blood and stringy mucus. Every case had movements of this nature at some time during its course. A marked change in the character of the stools seldom took place until close to the end of the disease. Even when constipation supervened the movements would continue to present the same characteristics with the exception of the size and consistency. A reliable indication of beginning recovery was the appearance of some solid, brown fecal matter in the stool. Strings of mucus were present uniformly from the first few hours, and always could be found in the stool, especially in the morning, for several days after every other symptom had disappeared. In the Everitt case it was seen as late as November 10, and I considered the child well early in October. The quantity in a single stool varied from a few strings, through the average of a drain or two, to as much as several ounces. The last of a series of rapidly successive movements, especially when accompanied by tenesmus, often consisted of but little else. Blood appeared early, at first as a few bright streaks, the amount increasing rapidly. In some movements, especially if the quantity was great, it was bright, but usually it was dark and tarry. The average amount in a dejection was a drachm or two. Sometimes the stools were of bright blood alone. Eight times—twice in one patient—the amount of blood voided in single stools was over two ounces.

In the earlier cases, the administration of bismuth resulted in nasty black stools streaked with blood

and mucus, and of a most offensive smell. As a rule, there was very little odor from the dejecta.

After it had been controlled once, a recurrence of the diarrhœa was experienced only by patients who too soon abandoned the restricted diet, or in whom constipation had been permitted to occur.

Next to diarrhœa, tenesmus was the most striking intestinal symptom. Usually it began early and ended with the diarrhœa. In fourteen cases it was never present, in thirty it was slight, in the others it was well-marked or severe. Children between the ages of five and fifteen appeared to suffer more from it than did others. Several times a child remained three or four hours on the bed-pan and got relief only when exhaustion resulted in sleep.

Constipation was a common occurrence during convalescence, but never during the acute stage unless the result of over-drugging. Even when the patient was constipated, the stool consisted of fecal matter, mixed with blood and mucus.

Fecal incontinence was present in twelve cases, all children. As a rule, it was of short duration, but twice it persisted over five days. It appeared only after the disease had continued a number of days and exhaustion had become marked. In five of the cases the symptom was not developed until after a marked toxæmia had supervened.

Abdominal pain was present in every case, its intensity varying greatly. In many instances it was out of proportion to the other symptoms, some bad cases evincing very little, several mild cases complaining bitterly of its severity. As a rule, it began early and augmented rapidly. Pain in a phlegmatic boy of twelve which is not controlled by half a gram of morphine given hypodermatically is severe. Patients complained more of this symptom than of any other. During the first day it was colicky and intermittent, soon assuming the form of a constant, sharp pain with cramp-like exacerbations. A paroxysm of pain frequently preceded a stool. Indefinitely situated over the whole abdomen at the outset, it promptly became localized and fixed over some part of the colon, becoming more general again only with the occurrence of abdominal distension. It is an interesting fact, that the ingestion of food, even of the blandest sort, promptly caused an exacerbation of the pain. A majority of the patients complained more of this symptom in the forenoon and after a period of sleep. Happily, it was unusual for the pain to continue to be severe throughout the disease. When the course had reached its height corresponding evidently to the maximum of local pathological changes, pain diminished rapidly, to become troublesome again only as the result of a relapse, or of some mismanagement of the case. Of all symptoms, I think abdominal pain was most ameliorated by curative measures.

Tenderness on pressure over the colon was present regularly and in proportion to the severity of the other symptoms. The sensitiveness of the swollen gut, easily mapped out beneath the retracted abdominal wall, contrasted with the insensibility of the other abdominal viscera. It was possible to palpate freely the center of the abdomen, but the least pressure over its sides or upper border elicited an expression of great pain. This symptom was persistent and outlasted the others.

Abdominal distension occurred in but 8 per cent. of all cases. In one fatal case it was severe; in the others it was of small degree and of short duration. Retraction commonly resulted in the longer cases from the great emaciation.

Strongly fetid breath was the rule for older children and adults, together with a dry, glazed tongue and a parched appearance to the bucca mucous membrane. A white-furred tongue accompanied vomiting. Herpes labialis was present in three cases.

Vomiting was the rule for infants, though not of a severe type. In others it was present in 16 per cent. of cases. It began most often about the second day and ceased early. In a few cases—the Everett child for instance—it persisted almost to convalescence. The vomited material consisted usually of stomach contents, rarely it was bile-stained; it was never fecal. Nausea without vomiting was marked in only six cases.

Singultus was present eight times, all the patients being infants or young children.

The temperature was relatively low even in the most severe cases. It ranged between 99° and 102° F. Only five cases gave a higher mark. The four highest marks were 103.2° F. twice, 103.8° F., and 104° F. In eleven instances the mark was subnormal, each time in a case presenting marked toxic symptoms. In one fatal case, after an initial rise to 101.2° F., lasting thirty-six hours, the temperature dropped to 97.4° F., and remained at about that point to death. The average duration of the subnormal temperature in these eleven cases was five days. As a rule, there was but little difference between the morning and evening marks. A return of the temperature to normal usually antedated the abatement of other symptoms and was of little value in determining a prognosis.

The pulse seldom corresponded with the temperature—it was more rapid and of poorer quality than would be expected. Except in very mild cases it was about 125 or 130 for adults, 140 for those under four years. Its quality was uniformly poor. In 68 per cent. of all cases irregularity or intermittence occurred at one time or another. One interesting feature was that it became poor early in the disease.

Respiration was rapid and shallow, deep breathing apparently augmenting the abdominal pain.

Symptoms of nerve origin were common in children. Convulsions occurred in 14 cases, 6 having but one paroxysm, 5 having two, and the others three or more. Delirium was seen in 19 cases, almost always passive or muttering. Marked coma was developed but four times. Extreme restlessness was a regular feature. In one fatal case the boy picked his skin until it was covered with excoriations. In another instance picking at the bedclothing was observed.

Absolute anorexia from the outset gave place to great hunger as recovery began. Piteous appeals for food made by adults as well as by children sometimes made it a difficult matter to continue the rigid abstinence essential to an undelayed recovery. Tonics for the appetite were never needed after recovery.

Marked prostration was a prominent and decided feature of the disease, and was, in its excess, out of all proportion to the other symptoms. It was great and increased rapidly as the disease continued. The patients appeared to be the victims of a toxæmia which prostrated them early and rapidly exhausted their vitality. Nearly every patient, excepting the mildest cases, voluntarily kept to his bed until recovery was well advanced.

As might be expected, rapid emaciation and a progressive anæmia kept pace with each day's continuance of the malady. This was more rapid and extensive than the loss of flesh which results in typhoid and other diarrhœal diseases. I can recall at least a dozen instances in which previously robust infants and children became but little more

than skeletons within four or five days, such a loss of weight as would result from not less than three weeks of gastroenteritis. One robust adult, a sturdy stone-cutter, lost twenty-eight pounds during an attack of ten days' duration. Of course some of the loss in these cases was due to the scanty diet I permitted.

A diminution in the amount of urine passed was found in all cases of which a record was kept, and the amount voided could be determined with sufficient accuracy. Eighty per cent. of the specimens examined showed at least a trace of albumin. Vesical paralysis was present for three days in one case.

The complications observed were numerous. Four patients had prolapsus ani—two infants, a boy of six, and a boy of eight. In only one case, an infant, was it severe and of prolonged duration. Bedsores were troublesome all of the seven times they were present, and appeared to be due to depressed vitality alone rather than to careless nursing. They responded very sluggishly to treatment.

Acute endocarditis developed twice, once for the first time in a boy of fifteen, the mitral murmur remaining up to the present time (January, 1903), although the dysentery was cured early in September. In another case, a girl of eight who had made, only a few months before, an apparently perfect recovery from an endocarditis complicating scarlet fever, the heart trouble reappeared.

Once there was a marked enlargement of the right parotid, once a moderate swelling of both glands. Two children had a mild varicella; two developed pertussis during convalescence. One boy of eleven, during convalescence, had repeated attacks of hysterical contractures of one arm and leg. Before his attack and since his recovery, he has never shown the first symptom of functional nervous disease. Bronchitis of a mild grade, complicated thirteen cases, but pneumonia was not present in a single instance.

Relapses occurred thirteen times and were due in every case either to errors in diet or to the too free use of opium or bismuth with resulting constipation. In one instance, each of two efforts made to feed an asthenic patient resulted in a return of the symptoms.

The average duration of the disease was 5 days for the mild cases, 4 weeks for the more severe ones. One case lasted 9 weeks, another 7, a third 6 weeks and a half, a fourth 6 weeks. Of these, three had been badly managed during the first two weeks. Of all the cases which lasted four weeks or over, 78 per cent. did not come under treatment until symptoms had been present at least three days.

The fatal cases numbered four and did not include two, one a man of seventy who could not be managed at home and was removed to St. Joseph's Hospital, Yonkers, after an illness of four days; the other, an infant of a few months, who died without medical attendance on what was probably the second day of the attack. An autopsy was made on this case and the typical lesions found.

The first patient to die was about two years old, sister of the infant that died without treatment. The second was a sturdy girl of seven, who at the outset presented symptoms of moderate severity only. On the second day a marked toxæmia became evident. It increased rapidly, collapse supervened, and the end came on the fifth day. The third was a girl of two years, who died on the second day, twelve hours after treatment had been instituted. Here, again, a toxic poisoning appeared to be the determining factor. The fourth, a boy of nine, brother of the girl just mentioned, died on the eighteenth day. For ten days he did well, then began a rapid decline, which ended in extreme emaciation, profound anæmia, and a fatal exhaustion. In this case, when the outlook became bad and treatment availed nothing, I abandoned my routine method and endeavored to feed the patient. The nourishment was not badly borne, although it aggravated the diarrhœa, yet it did not avert a fatal outcome.

These four cases made the mortality 1.17 per cent.; including the other two deaths, the rate was 2.5 per cent. The register of the Health Board shows that there were in all twenty deaths from dysentery in the town of Eastchester during the epidemic. There were in addition at least six deaths on the Yonkers side of the Bronx. Having no way of estimating the total number of cases, I cannot estimate the mortality rate for the whole vicinity. It is an interesting fact, that the vital register shows but two deaths from other diarrhœal diseases during the epidemic.

All efforts made to cure the disease were based on the indications to free the intestine from the causative microorganisms—which have been determined since to be the Shiga bacilli—and their products, to prevent their reintroduction and growth, and to heal the lesions already developed. At the same time, symptomatic measures were demanded urgently, to give relief from the pain and tenesmus, to lessen the number of movements, to minimize the wasting and rapidly progressive prostration, and to aid the exhausted and toxin-poisoned nerve-centers.

No drug nor remedial measure—and I tried faithfully all I could find properly vouched for—acted as a specific. Ipecac has been exploited to be such. I tried the drug conscientiously in the earlier cases. It gave uniform disappointment, whether given in small, frequently repeated doses or in a few large doses, the former doing nothing more than to cause a loss of valuable time, the latter only aggravating the symptoms by producing the unpleasant physiological effects of the drug.

When a case was seen at the very outset—within the first few hours—active catharsis, together with fasting and absolute rest, frequently seemed to abort the disease and end it within three or four days. This was true of very young children, as well as of adults. To substantiate this assertion is the fact that practically no short cases were seen early in the epidemic, while after this plan of treatment was adopted, a prompt recovery without the development of severe symptoms sometimes resulted. The patient was put to bed and given, if very young, ℥ ss of castor oil with gr. ¼ of calomel, repeated twice at intervals of four hours; to an adult, an initial dose of ℥ ss castor oil with gr. ii of calomel was given, then two doses of ℥ss of the oil and gr. ss of calomel at four-hour intervals. Eighteen hours after the last dose, if any pain, characteristic diarrhœa, or tenesmus remained, one or two grams of calomel, according to age and in divided doses, followed by a saline laxative, were given. If, on the other hand, no symptoms but a slight fecal diarrhœa remained, as well as when a similar condition was secured by the second purgation, three or four full doses of powdered opium were administered. From the outset, water and unflavored tea were permitted as freely as the patient would take them, but no food of any sort, with the exception of a little rice water diluted with lime water and small doses of whiskey. I could not believe that irrigations were an essential part of this treatment nor that they gave material aid in an effort to abort

a case, and for that reason they were not employed as a part of the plan. It seems to be unaccountable that these colon flushings, which were invaluable during the cases running a longer course, which catharsis had failed to abort or accomplish an equal result, would not promptly abort a case when properly employed from the very inception of the disease. This opinion was arrived at reluctantly and only after careful observation.

When a case was seen late, or when by its severity at the outset an attempt to abort it would have been but a waste of time—in other words, when the local pathological changes were well marked—the first indication was to secure as complete an emptying of the digestive tract as possible. The desire not to augment the prostration, contraindicated such active purgation as I have just described. Castor oil gave the best results of all the cathartics tried, and contrary to what might have been expected, it did not appear to aggravate the abdominal pain and tenesmus. When adults were unable to take it, I substituted citrate of magnesia with good, yet less satisfactory, effect. It was found to be well not to stop with one dose of the cathartic, but to continue its administration in small doses until scybala and undigested food were no longer to be found in the stool in any but a small amount.

The employment of colon irrigations of one sort or another, was the measure which had the greatest curative effect. I am sure, the cases which did best were those in which this procedure was carried out most carefully and persistently. Not having time to do more than superintend its employment in any but the very worst cases, I was obliged to depend upon the nurse or relatives after a preliminary lesson or two, so that I never knew just how punctually and correctly the flushing was done. When properly carried out, it kept the bowel comparatively free from irritating accumulations, it prevented the growth of the bacilli, the production and accumulation of their toxins, it brought antiseptic solutions in contact with the organisms, it carried astringents to the numerous ulcers. Its use lessened greatly the number of stools, relieved the pain and tenesmus, and controlled the toxæmia. For the purpose of cleansing alone, nothing answered better than decinormal salt solution. When an astringent action was desired, tannic acid accomplished most, and tannic-acid solutions, according to Hare, are antiseptic.

The technique of these injections I made as simple as possible, and I know I secured better results than when too many fussy details resulted in annoying the patient—terrifying him if a child—aggravating his pain and increasing his exhaustion. To turn the patient on his side and elevate his hips is not necessary. After a little experimenting, all I did was to slip a douche-pan under the buttocks. Nothing but a fountain syringe was ever permitted, and for its tip a soft rubber catheter with several additional holes cut in its sides. In a few cases I tried the hard-rubber return-current tube, to find it less practical and efficient than the catheter. In the earlier cases I endeavored to introduce the catheter into the sigmoid-flexure at the cost of much labor to myself and the nurse, annoyance to the patient, and with but little success. By chance I found a statement made by Johnston of Washington, that "colored fluid forced into the rectum under gentle pressure escaped in half a minute through a fistulous opening in the right iliac region." Subsequently, I directed that the catheter be inserted only four or five inches beyond the anus with just as good results. Gentle pressure was another essential to success, for when the bag was elevated too much the rapid inflow of fluid set up a too active peristalsis. The temperature of the solution employed was always made as high as the patient could tolerate without decided discomfort. For each irrigation, whether for infant or adult, four quarts of saline solution were used. This was permitted to flow out of the rectum by the side of the catheter. If a return had not begun after the introduction of three or four pints of the solution, or when the patient complained of a sensation of distention, the tube of the syringe was removed and the fluid permitted to escape through the catheter left in the rectum, after which the inflow was continued. I found that it did harm to permit the patient to make expulsive efforts during or after the completion of an irrigation. If the catheter was permitted to remain in place, practically all the fluid returned within a few minutes. Patients, even small children, soon became so accustomed to the procedure, that it could be carried out without any trouble. Of course, a few badly trained children with mean dispositions never became reconciled to the measure.

The solution employed and the frequency of its use was determined by the character of the diarrhœa. The lightest cases were given a saline irrigation after each movement, and always three a day. A case of moderate severity having daily from six to ten movements was given a saline after each stool, while night and morning the saline was followed by one or two quarts of an antiseptic solution. When the movements were exceedingly frequent a saline was given every three hours, every other irrigation being followed by a quart of water containing from 2 to 4 drachms of tannic acid. A few patients experienced so much pain after the employment of this solution that it could not be used. Tannic acid was of service also when the quantity of blood in the stools was excessive. As the diarrhœa lessened and its character changed, the number of the irrigations was reduced, but in every manageable case two salines a day were given for at least three or four days after recovery.

The value of these irrigations I cannot rate too highly—in fact, upon them and upon the diet I depended for best results. Twice I saw an exhausted child fall asleep during the flushing after a prolonged period of pain and tenesmus. Frequently little children asked to be given an irrigation, realizing the relief it would bring.

Next to the irrigations I found a rigid restriction of the diet of the greatest service. After trying many things I finally allowed all patients, whether infants or adults, nothing but rice water diluted with lime water, backed up by liberal doses of peptonoids and whiskey or brandy. This meager diet was continued without variation until convalescence had been well started. All other forms of light or fluid diet gave trouble at one time or another, this never did. When vomiting was present peptonoids and creosote were given. Perhaps my observation has been in error, but I do feel that if any one article of diet is to be avoided in this disease it is milk, so repeated and marked were the bad effects I saw follow its use. Several times I saw a relapse after its ingestion, even when the patient was practically well, a similar effect not so commonly resulting from a return to the use of other foods. Two of my most protracted cases were ones in which the patient would have milk. Twice I saw recovery begin immediately on stopping the milk in cases in which the patient had been permitted to have it. The first patient I lost was a bottle-fed infant whom I had brought almost to a cure. The movements had become about normal, the other symptoms had

disappeared. Not trusting the mother, I cautioned her to give the child nothing but rice water and peptonoids. Early the next day I was summoned in great haste to find that all the symptoms had returned in an aggravated form and the infant in collapse. Immediately after my departure the preceding morning, the mother had given her "starving" baby a bottle of milk, administering a second dose in the afternoon. The child never rallied, and died twenty-four hours after my hurried visit. I am sure it was not tyrotoxicon that did the harm. I know of a few patients who did well on milk, but they were the infrequent exceptions.

To 92 per cent. of all patients, whiskey or brandy was given as a substitute for other food. They were well borne; they did not aggravate any of the symptoms. Had they not been exhibited in large doses I believe exhaustion would have ended fatally many of the longer cases. To say the least, they made possible the employment of the starvation diet I found so essential to a good recovery.

The internal administration of bismuth and other astringents of service in simple diarrhœas gave me no results of value. In large doses they lessened the number of movements, but at the same time they made the stools pasty and offensive, elevating the temperature and aggravating the other symptoms. They seemed to cause the accumulation of waste products in the intestine and thus encourage the growth of the bacilli. In protracted cases, when diarrhœa was the only remaining symptom, I thought nitrate of silver in pill form of some service. In the acute stage I could not determine it to be of any value. Intestinal antiseptics—I tried all the more reliable ones—gave but indifferent results. From salol I thought some infants derived benefit.

The abdominal pain always demanded attention. In a few instances the application of turpentine stupes to the abdomen, the application of ice, or the alternate use of the two sufficed. In all cases they aided, if not in relieving the pain to any great extent, in reducing the hyperæmia of the colon when applied over its course. To control the severe pain experienced by many patients nothing proved adequate excepting opiates. Morphine, given hypodermically, acted best not only because its administration could be more accurately controlled and its sedative effects were more pronounced, but also because it had less effect on the digestive tract. I never employed it unless the pain was severe, and then I secured the best results when I gave it in large doses and at long intervals. Not once did toxic effects follow its administration, even to young children in large doses. At best morphine always had a tendency to cause constipation, so that I usually followed its exhibition with a small dose of castor oil. Some writers advise the use of opium as a part of the routine curative treatment. After employing it thus in a large number of the cases I found it of no value. When it produced any marked effect it invariably caused a retention in the intestine of irritating fecal matter with a resulting exacerbation of the symptoms.

For the relief of tenesmus I tried all the usual measures, including small enemata of starch and laudanum, but I found that the systematic and careful employment of irrigations did more to relieve this distressing symptom than all else.

Vomiting, as a rule, did not require special treatment after the diet had been regulated. Sinapisms to the epigastrium were often adequate. In a few cases it was severe enough to call for the use of antemetics, small doses of bismuth subnitrate and cerium oxalate answering the purpose as well as any, for this symptom appeared to be reflex and ceased when the other symptoms began to abate.

The systematic continued use of purgatives is not recommended, yet I found three cases which did better on small bi-daily doses of castor oil than on anything else. The Everitt child, already mentioned, began to mend after many tedious weeks so soon as I began to give the oil. When at any time during the disease the colon flushings did not keep the stools free from undigested food or an excess of mucus, the administration of a small dose of castor oil or of a saline laxative promptly rendered the movements of better character.

In reading over the histories I was surprised to find that, with the exception of the fatal cases and those complicated by endocarditis, I had used cardiac stimulants other than alcohol but seven times, and this in spite of the severity of many of the cases.

Whenever I could get the attendants to carry them out, the plan of nursing and the methods of disinfection resorted to in typhoid fever were those made use of during the epidemic, the only difference being that extra precautions were taken with the food. All drinking water was boiled, the rice water freshly prepared and kept in sterilized air-tight containers. During convalescence no uncooked food was permitted.

The five most interesting features of the epidemic were its extent; the abrupt onset of marked symptoms without prodromata; the great prostration occurring almost at the outset; the severity and long duration of many of the cases; and the marked value of colon irrigations and a narrowly restricted diet as remedial measures.

Addenda: During the summer of 1903 there were not more than ten cases of the disease in this whole vicinity where the malady had been epidemic the year before. The cases were very mild and yielded promptly to treatment. In three of them serum was tried, but its value could not be determined.

USE OF SERIES SPARK-GAPS FOR X-RAY WORK.

By L. WEISS, M.D.,
NEW YORK.

The advancement of radiography has to a great extent been due to improved methods of technique, but mainly to the improvement in the apparatuses used. Comparing the first *x*-ray picture of nine years ago, by Professor Röntgen, necessitating an exposure of about two hours with those of to-day, necessitating an exposure of a like number of seconds, one readily sees how rapidly this art has advanced.

A few years back there was doubt in the minds of many as to the most efficient apparatus to use in order to generate current for the *x*-ray tube, and there were as many to contend that with the static machine as good and as rapid work could be done as with the induction coil. To-day it is undoubtedly conceded that the large induction coil is the apparatus that excels by far in every respect every other form of apparatus used to energize the Crook's tube. Of course, where light work is to be done, as radiographing the hand, arm, foot, or leg, a static machine with at least ten revolving plates of thirty inches diameter, in the hands of an expert operator will do good work, but the exposures must necessarily be much longer than those of a coil in competent hands; but when radiographing the shoulder, hip, pelvis, or foreign body in the kidney, bladder or gall-bladder, one must necessarily have a coil of spark capacity of twelve to eighteen inches in order to do the best work; no

static machine can possibly compete in this work with a fifteen-inch coil.

The art of making a fifteen or eighteen-inch coil

Fig. 1.

was quickly learned, and to-day all first-class manufacturers make good coils of these spark lengths, and sell them with a guarantee against breaking down when properly used, and so made as to give a heavy hot spark, which is so essential to do instantaneous work. But the difficulty to be overcome was to make a tube that could withstand the full output of so large an apparatus, and to-day there are hardly any tubes made that can stand the full output of a fifteen-inch induction coil, where fifteen amperes of current are thrown into the primary (when the Wehnelt interrupter is used) that will be able to take care of this current for longer than one half to one minute, without breaking down the vacuum if the current is run from the terminals of the coil directly into the tube; for so large a current rapidly heats the tube to such an extent as to destroy the vacuum. Then again, besides the risk of destroying the vacuum, the inverse current generated by the induction coil has a tendency to blacken rapidly the tube, and I have time and time again deeply colored a tube by throwing in a large amount of current even for so short a time as a minute.

It is an obvious fact that we can easily take a picture of any part of the body in a few seconds if we can get a large enough coil with sufficient output of a hot spark, and can get a tube to stand this without breaking down the vacuum; for when the vacuum is broken down, the tube will not work again, unless it is reexhausted. Sometimes if the tube is carefully watched and the current hurriedly shut off just as soon as the vacuum starts to go down, which will be observed by a purplish hue interspreading itself about the green fluorescence, the tube in a few minutes will recuperate, and with gradual "working up" will again be in condition for use.

As the tubes made will not stand the output of a powerful coil, how was the problem to be solved of throwing so much current into a tube and doing this instantaneous radiography?

The main reason the tubes will not hold up with these large currents is on account of the inverse current generated by the coil; now this inverse current is hardly apt to jump over an air space of from one to two inches when placed in series with the terminals of an induction coil, and it is mainly this inverse discharge that causes the rapid heating of the anode, and the discoloration of the tube (which discoloration is due to the disposition of the metals of the electrodes of the tube on its glass wall), why not make use of such a spark-gap and keep away most of this inverse discharge from the tube and so eliminate to a great extent these harmful qualities of the current.

I found by experimenting, that one and three-quarter inches spark-gap was sufficient to overcome this on my coil, and devised a gap that could be so adjusted as to give a gap from a fraction of an inch to two inches, so that those using smaller coils could adjust this gap to meet their requirements, for on smaller coils, one inch to an inch and one-half would suffice, while on an eighteen-inch coil about two inches will be necessary.

I have tried a large number of tubes and found that without these series spark-gaps I could start to break down the vacuum in from fifteen seconds to one minute's time; when working the coil with less current, the anode would get hot in a few minutes, but when using the gaps, the anode would not get hot in twice and three times that length of time, when the same tube and same amount of current were used.

In addition to preserving the vacuum, preventing

Fig. 2

the rapid heating of the anode, and discoloration of the tube, I found that the spark-gaps greatly diminished the length of time necessary for radiographic

exposures, and that the resultant radiograph was much better, as is shown by the accompanying pictures; for the spark-gaps send the current through the tube with greater force and so act as condensers. The spark-gaps also have a tendency to push up the vacuum of the tube, so it is necessary to use a low tube, and it is just this kind of a tube that enables us to get the largest output of rays, rich in photographic effect.

The hand in fig. 1 was taken without gaps in six seconds, and that in fig. 2, with gaps, in one second, and the plate of fig. 2 was much better than of fig. 1. In the case of a hip, one picture was taken in forty-five seconds, with the gaps, and a second without gaps, in one and one-half minutes; in this case, in order to prevent the current from destroying the tube, I exposed for forty-five seconds and shut off the current, and keeping the subject in the same position, after a few minutes when the tube had cooled, I again threw in the current for another forty-five seconds.

The time of exposure necessary for good pictures with and without the spark-gaps for various parts of the body, with a subject of about 150 pounds, with the same amount of current, same *x*-ray plates and

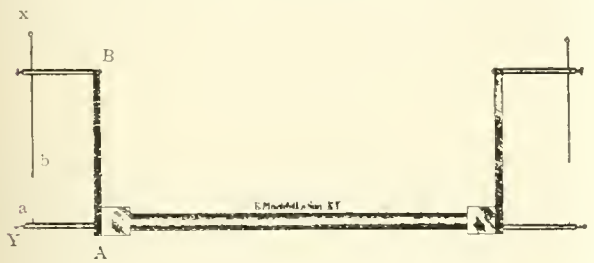

Fig. 3.

developer, same tube and same apparatus, was as follows:

	WITH GAPS	WITHOUT GAPS
Hand,	one second	six seconds
Elbow,	one second	fifteen second
Shoulder,	ten second	thirty-five seconds
Knee,	six seconds	thirty sesonds
Hip,	forty-five seconds	one and one-half minutes

Description of the Gaps.—The most convenient way is to mount these spark-gaps on a wooden rod about two feet long, and put one gap arrangement on each end. By means of a clamp, the wooden rod can be attached to any *x*-ray stand, and while at the same time supporting the gaps, it acts as a separator of the conducting cords. The clamp I use allows of almost every sort of arrangement of this supporter to conform with the arrangement of the position of the *x*-ray tube.

On each end of this wooden rod, I have mounted a piece of hard rubber about one-quarter of an inch thick and five inches long; and on this hard rubber, four inches apart from one another, are two upright metal posts, which are respectfully three inches high. Post A has a pointed edge to receive the current and also a loop for the conducting cord; post B has a hole drilled through its upper part, through which a metal rod slides, which is five inches long; it has one end pointed to transmit the current, and at the other end is a loop for the other conducting cord.

This sliding rod can be adjusted, from the point on post A, any distance from a fraction of an inch to two inches, and in this way any size spark-gap can be obtained up to two inches to suit the needs of each individual apparatus. A set-screw holds this rod firmly in place at the point of selection. Conducting cords run from each terminal of the coil to the loop on sliding rod at X, and another cord runs from loop Y, on top of post A, to the respective terminal of the tube. It is essential that posts A and B be separated fully four inches, for otherwise the hard rubber has a tendency to carbonize, and, acting as a conductor, prohibits the proper working of the spark-gap.

The advantages of these series spark-gaps are:

(1) The tube can stand the full output of the largest coil with the vacuum remaining constant.

(2) The tube is kept almost entirely free from blackening.

(3) The anode is kept from readily becoming hot.

(For these three reasons the life of the tube is necessarily prolonged).

(4) A richer volume of *x*-ray is produced, and so exposures of radiographs are greatly reduced.

A NEW OPERATION FOR PYOTHORAX.*

By SPENCER GRAVES, M.D.,
ST. LOUIS, MO.

I wish to present an operation which seems to me practical—for the purpose of preventing deformities in some acute cases of empyema, and for causing a more uniform and anatomical closure of the suppurating cavity in chronic cases. In all cases the most serious consequence of the affection is deformity, and in children lateral curvature of the spine is likely to occur. I find, after looking up the literature on the subject of empyema, that the operation I shall describe, probably differs from those heretofore practised.

Resection of one or two ribs, solely for the purpose of drainage, usually cures acute cases, but the patient is often left with more or less deformity. The wound is extensive in thoracoplasty, "Estlander's operation," and it probably entails the removal of more of the bony wall than is necessary. The following case suggests the advantage of the operation I request you to consider:

Miss R., age sixteen years, consulted me about the first of January this year. She gave a history of pneumonia in May, 1903, continued illness, and the formation of a swelling a little below and to the right of the left breast, which opened and had continued to discharge pus. She was emaciated and presented generally the appearance of a consumptive. Temperature 101°, pulse 110.

With the history, after making physical examination, there was little difficulty in determining that the pus discharging from the sinus came from the thoracic cavity.

A transverse incision was made over the sinus, which was between the fifth and sixth ribs, about two and a half inches below nipple on left side, with the intention of locating the opening into the cavity, and introducing a probe to determine on a site for drainage posteriorly.

When the elevator was introduced under the sixth rib to raise it, the rib broke. I removed the sternal end of the rib because it was necrotic, then extended my incision, following the rib and removing sections for convenience till I came to periosteum that appeared sound. I removed the sixth rib to the posterior axillary fold, and located the sinus near this point. I then sutured the wound, except at the site for drainage, enlarged the opening and introduced a short rubber drainage-tube. The lung seemed to expand feebly and a large quantity of pus was discharged. After the second day cavity was irrigated daily with permanganate of potassium solution.

There was nothing in the condition of the patient worth noting, until about ten days after the operation. At this time I observed my opening for drain-

*Read at the annual meeting of the Missouri State Medical Society, 1904.

age was getting smaller rapidly in spite of my efforts to keep it open. On January 29 a probe could not be introduced into the opening, and the general condition of the patient was not so favorable.

I arranged immediately for the second operation. I found, on the operating table, that drainage was shut off by the fifth and seventh ribs coming together. I resected part of the fifth rib for the purpose of drainage. Treatment was continued as before. The discharge ceased in about ten days. The patient went home cured and in pretty good general health, three weeks after the second operation. There is absolutely no deformity, aside from the uniform sulcation where the rib was removed.

My experience with empyema since the case just reported, is limited to three cases. One was tuberculous. The second case was that of a girl aged fifteen; I assisted Dr. Dean in the operation. This consisted in the removal of about an inch and a half of the ninth rib in line with the angle of the scapula. Dr. Dean informs me that the patient's recovery was satisfactory, but that the deformity is marked. He at the same time remarked that he regretted not having removed rib anterior to the opening for drainage.

The third case was one of acute empyema following pneumonia. Patient a girl, aged fourteen years. About an inch of the seventh rib was resected below the angle of the scapula. An incision was then made in the pleura, and a long probe used to aid in determining the size of the suppurating cavity. I then extended the incision horizontally over the seventh rib, and removed the rib to the costal cartilage. After suturing this wound, I resected about an inch and a half of the eighth rib. The opening was then enlarged and a short drainage tube introduced into the cavity. The after-treatment was the same as was carried out in the first case. The patient made a prompt recovery without deformity. I removed the rib anterior to point selected for drainage, as I did not consider it necessary to remove the entire rib in an acute case.

The object of this preliminary report is to submit for consideration this operation. Removal of the entire rib anterior to the opening for drainage, which should be as near the posterior wall of the suppurating cavity as possible, the purpose of this being to prevent deformity; and resection of rib above or below, for adequate drainage in some recent cases of empyema. Removal of entire rib, if necessary two ribs (except the head), with resection of one for drainage in chronic cases, for the purpose of contracting suppurating cavity, which persists because of the thickened pleura and unexpanded lung. The rib removed should be the one passing over the center of the cavity, or one a little below this point.

The removal of the rib as suggested seemed to be followed by the ones above dropping lower, the cartilage bending and the change taking place without deformity. Just what all of the forces are that work to bring the rib above and the one below the rib removed together, I cannot explain. The deformity seems to be due to nature's effort to close the cavity, which is often too much for the granulating process. I believe the operation to prevent deformity is indicated when the suppurating cavity is large, and other conditions which indicate probable deformity are evident, and in cases of long standing.

In many cases there are evidences of beginning deformity when the surgeon is called, which was the case with Miss R. The operation seemed to correct as well as prevent deformity in this case.

The operation is simple and can be rapidly done. The sutured wound heals in a few days. It is very little if any more trying on the patient than operation for drainage. I am sorry not to have had experience to justify my belief that removal of one or two ribs (except the head) will prove a cure for some cases that have existed for a longer time than the one reported.

It makes no difference what incisions are made. Estlander's operation is extensive and is followed by great shock, and we must depend on atmospheric pressure and contraction in all directions to close the cavity, as all of the bony wall over the cavity is removed.

The sixth rib will generally be found to pass horizontally over the trough-like cavity a little below the middle. As the chest more readily contracts at this point than lower down, I believe in the majority of cases it will be found better to remove the sixth rib.

3603 Lindell Boulevard.

A CASE OF FOREIGN BODY REMAINING IN THE LENS OF THE EYE FOR SIX YEARS WITH THE LENS OTHERWISE CLEAR.

By FRANK N. LEWIS, A.M., M.D.,
NEW YORK.
SURGEON TO THE MANHATTAN EYE AND EAR HOSPITAL.

A foreign body lodged inside the eyeball is usually considered to be a source of danger, not only to the injured eye, but also a possible cause of sympathetic inflammation of the other eye, starting up within a short time, or sometimes after many months or years. For this reason it is the practice as early as possible to use every effort to remove the foreign body. The satisfactory results in many cases following the use of the magnet, or that combined with other means, makes these cases always interesting to the oculist, and is a cause of much gratitude on the part of the patient.

Many patients in whom a piece of iron or steel has been removed from the interior of an eye, have recovered with good vision, and all possible danger of inflammation seems to have passed. Other cases, in which inflammation has ensued, although the foreign body had been removed, have gone through with the inflammation, and the vision is lost, but the eyeball presents a good appearance and the patient is saved from enucleation. Other cases still are not uncommon in which a destructive inflammation follows, even if the foreign substance has been removed and all possible treatment used to allay inflammation.

No doubt the condition of the foreign body, as to whether it is infected or not as it enters the eye, has much to do with the subsequent history. Even if the foreign body is at once removed, a severe infection may have taken place, which it is impossible to prevent spreading and ultimately destroying the eye. Again, it seems in some cases as if the foreign body may have been aseptic, and very slight or no inflammation has followed, or possibly, by becoming encapsulated, the foreign body remains in the eye for years without setting up inflammation.

There seems to be no limit as to time when a foreign body may set up a severe inflammation. Within a few hours of the injury much inflammation may be present or, as in some cases reported, many years may elapse before a foreign body will start up any trouble.

The location of the foreign body inside the eyeball, too, may have an important bearing on the

case. The point of entrance is another important factor. If the point of entrance or the foreign body is in the ciliary body, it has seemed, in the writer's experience, to be especially dangerous. Foreign bodies which enter through the cornea, or those which pass through the eyeball and are lodged in the posterior part of the sclera, may possibly not set up as severe inflammation as those affecting the iris or ciliary body. Foreign bodies that are lodged in or have passed through the lens almost always produce a traumatic cataract. This usually begins a short time after the injury, so that in twenty-four hours there may be much opacity of the lens. The age of the patient may have much to do with the rapidity with which the opacity increases. The hard lens of old age will naturally not become as rapidly opaque as the soft lens of early life. If the wound of the lens capsule is large, we may expect a more rapid development of the cataract than where the wound is small, the former allowing more aqueous to enter the lens substance.

The most common of the small substances that enter the eye are particles of iron or steel, which are driven in while one is using some instrument in hammering. Others are bits of brass, copper, or particles of glass. It has been considered by some that pieces of glass are less likely to set up a destructive inflammation.

But when all the various conditions, as to location of the wound and of the foreign body in the eye, the size, the material, and the duration of time since the injury, are considered, it would seem that there is only the one and almost invariable conclusion that a foreign body in an eyeball is a dangerous thing, and should be removed at once if possible.

In view of the above facts, and of the practice of at once removing a foreign body from the eyeball, when possible, which is my plan, in common with that of all, I believe, the following history of a case of foreign body may be worthy of record: Although the patient was seen within a few days of the injury, and the foreign body was readily located lying in the lens, on my advice no attempt was made at that time, nor has any effort been made since, now over six years, to remove it. While this may seem an unusual proceeding, after giving the history of the case, the reasons for so doing will be considered.

Fred A., twenty-six years of age, a machinist, in good general health, first appeared at the Manhattan Eye and Ear Hospital on November 11, 1897. He stated that while using a chisel on a piece of steel, one week before, a particle flew up and struck the left eye. Practically nothing was done in the way of treatment until he came to the hospital. On examination there was found slight redness of the eyeball, but no marked tenderness and no pain, and very little photophobia. The vision of this eye was $\frac{20}{200}$. There was slight lacrymation. At the lower nasal part of the cornea was a small wound, but the rest of the cornea was fairly clear, the aqueous also clear, no iritis, and pupil acted normally. In the lens was seen a dark, glistening particle, a little to the supratemporal side and slightly posterior to the equator of the lens. It was irregular in shape and about 2 mm. in its largest diameter. From the history and the appearance it was thought to be a piece of steel. The lens was otherwise clear, and no changes from normal were detected in the vitreous or in the fundus of the eye. The right eye was normal and vision was $\frac{20}{15}$, and ability to read Jaeger No. 1, 5″ to 17″. The first impression as to treatment was to remove, if possible, this foreign body. For some reason the patient could not remain as an indoor patient at the hospital. The eye not being painful, and not showing the usual amount of irritation after such an injury, it was decided to watch the eye at the outdoor clinic. He was given a solution of atropine, two grains to the ounce, and iced application, and instructed not to use his eyes. It was expected that a traumatic cataract would soon develop and, as the patient's age was twenty-six years, it was somewhat unusual that at that time there was not some milky-white appearance. On the contrary, aside from the foreign body and a very minute wound of the anterior capsule, which could with difficulty be seen, the lens was clear. The patient was seen at frequent intervals and the eye carefully watched. Under this plan of treatment the eye became white and showed no irritation from the presence in the lens of the foreign body, no cataract developed, the tension remained normal, and the vision on November 27 was $\frac{20}{30}$. The eye remained quiet several weeks. On January 27, 1898, there was present a considerable amount of redness of the left eye, which the patient stated began a few days previous. But the congestion seemed to be that of a catarrhal conjunctivitis, with mucous discharge, and not the congestion with photophobia lacrymation, and little or no mucous discharge, which is seen as a result of a foreign body in the eye. There was no opacity of the lens other than the foreign body, the iris was clear, and vision as before $\frac{20}{30}$. The other eye was free from redness.

The patient was now admitted to a ward of the hospital and the eye treated with cleansing, iced applications, and a solution of argentum nitrate, five grains to the ounce. Under this treatment the conjunctivitis disappeared and the patient left the hospital in one week, on February 5.

The use of a solution of atropine in an eye is sometimes a cause of conjunctivitis, and, while in this case the atropine was used only enough to keep the pupil dilated, it is a possibility that it may have had something to do in starting up the conjunctivitis. Conjunctivitis from the use of atropine, however, usually shows a peculiar dryness, wrinkling, and redness of the skin of and around the lids, which was not present in this case.

The patient continued under observation and the eye remained free from redness and irritation, the vision continued as before, until February 18, two weeks later, when he was again admitted to the hospital for another attack of conjunctivitis. Under treatment with astringents, cleansing, etc., the eye again became white. The symptoms were so decidedly those of conjunctivitis, and not such as would be caused by irritation from the foreign body, that it seemed best not to attempt to remove the piece of steel from the lens. The vision remained $\frac{20}{30}$ and the lens continued clear. There seemed to be no doubt about the particle in the lens being a piece of steel or iron. Many different ones examined the eye, and I think all agreed that it was so. The use of the magnet was not attempted, for if it had been, and the particle dislodged, it was expected that opacity of the lens would follow.

The conjunctivitis entirely disappeared and the patient left the hospital March 9.

On June 9, 1898, the record shows that a foreign body was removed from the left cornea. Otherwise the patient has since had no ocular symptoms. He had continued his work as a machinist.

April 16, 1899, the condition of the eyes was as before. V.R. $\frac{20}{20}$ + V.L. $\frac{20}{20}$. Reads Jaeg. 1 with each eye. The foreign body in the lens is as when first seen.

The patient was thoroughly instructed as to possible symptoms in the future, that might arise as a result of the foreign body being in the eye. He is an intelligent man and seemed to appreciate

the situation and the necessity for immediate attention, if in the future the eye became in any way affected.

On December 14, 1903, over six years since the injury, he came to my office, in response to a letter of inquiry as to his condition. He had had no trouble with the eye, and it had remained free from any symptoms of irritation. The foreign body in the lens presented the same appearance as before, the lens otherwise being clear. V.R. $\frac{20}{20}$ +, V.L. $\frac{20}{20}$ +.

The question naturally arises, whether in this case it would have been or is now better to follow the usual practice, of attempting to remove every foreign body from inside an eyeball? While the possibility of future inflammation is fully appreciated, it does seem that this case is an exception to the general rule. The foreign body is very probably encysted, although no enveloping membrane can with certainty be seen. The eye may remain as it is during the entire life of the patient. Dangerous symptoms are less likely to arise from a foreign body in the lens than where it is lodged in some other part of the eye, such as the ciliary body. The danger of sympathetic ophthalmia in this case, while not entirely absent, is not, it would seem, very great. The patient is one who can probably be relied on to seek advice at the onset of any ocular symptoms. If a successful attempt is made to remove the foreign body we naturally would expect the formation of cataract, and, even the most satisfactory treatment for this would leave the eye in a far different condition as to useful vision. Seldom do we find that where one eye is normal, and the other eye, from which a cataract has been removed, work satisfactorily together.

Every case should be treated according to its individual indications, and a rigid following of set rules for any class of cases is not wise. It does not seem to the writer that it would be an act of wisdom or good surgery to attempt at present to remove the foreign body in this case. Even a successful operation to remove it would probably so impair the present normal vision that the eye would be practically useless. If at any time later there are symptoms of irritation, then certainly an operation to remove the foreign body will be indicated.

35 West Thirty-sixth Street.

A CASE OF CHRONIC FIBRINOUS BRONCHITIS, WITH ESPECIAL REFERENCE TO THE TREATMENT OF THIS DISEASE.

By W. MOSER, M.D.,
BROOKLYN, N. Y.
PHYSICIAN TO THE GERMAN HOSPITAL.

The patient, a man forty-eight years of age, had recurring attacks of severe coughing and dyspnœa. The expectoration which was frequently blood-stained contained rolled-up masses, which, when placed in water, showed the characteristic arborescent appearance. The tree-like appearance corresponded to the ramifications of the bronchi. Thus,from a larger bronchus the trunk was formed, while the finer bronchial ramifications represented the branches or twigs of the tree.*

The casts consist usually of fibrin, but may, according to Grandy and others, consist of mucin. They may be formed of both fibrin and mucin.

The patient first expectorated these bronchial casts about twelve years ago, with intermissions of varying duration. Since the patient came under my observation two years ago,he had repeated attacks, with intense dyspnœa.

The physical signs were those of ordinary severe bronchitis, with the exception that now and then slightly diminished respiration was noted on one side.

There was no perceptible difference in the percussion note of both sides, and the bruit de drapeau, described as a very fine dry râle, due to the vibration of a detached part of the bronchial cast was not satisfactorily obtained. The partially separated membrane may even cause a palpable thrill (Hoffmann).

With the onset of each attack the patient had a slight rise in temperature, varying from 100 to 101 F., with headache and chilliness

While fever is generally associated with the acute form, it will be seen from this case that it may occur with the chronic. Where the sputum is not carefully examined, this condition may be mistaken for malaria, as there may be a slight enlargement of the spleen.

The patient about fifteen years ago contracted a chancre, and is at present suffering with syphilitic myocarditis, ocular paralysis, and eruptions on the palms of the hands, and soles of the feet.

The etiology of this disease is not easily determined, and seems to depend upon different factors. Sokolowski found in four acute cases Staplylococcus pyogenes aureus and albus, and believes they stand in etiological relation with this form. Strauss found in his case the pneumococcus, Löffler's bacillus, streptococci, and staphylococci. Osler found in a case the aspergillus fumigatus. Bettmann found protozoa.

Mader regards pemphigus as an etiological factor. Fibrinous bronchitis is sometimes associated with skin eruptions, as in my case (syphilis).

Street's case was associated with herpes zoster and impetigo, and Waldenburg's with impetigo capitis. Small bronchial casts are sometimes expectorated in lobar pneumonia, and in asthma.

Fibrinous coagula, either ribbon-shaped or of cylindrical form, may be expectorated in various diseases; as, for example, in influenza, as noted by Roque, in typhoid fever (Souqué, Eisenlohr, Möller, Mazzotti), articular rheumatism (Degler) or pneumonia. Fibrinous bronchitis is sometimes, as in this case, associated with chronic cardiac disease. I do not, however, regard the myocarditis as a cause of the fibrinous bronchitis in my case, but am inclined to regard them both as dependent upon syphilis. Fibrinous casts have been seen in the sputum after tapping the pleura (Osler).

Fritsche describes a toxic form following iodine My patient, who had taken large doses of the iodides with mercurial inunctions, for his syphilis, was in no way relieved of his fibrinous bronchitis by these drugs.

McCullom has seen fibrinous casts of the trachea and primary bronchi expelled in diphtheria.

Mallory, Pearce, and Councilman found fibrinous membranes in the bronchi in forty-two fatal cases of diphtheria.

These cases, are of course, secondary fibrinous deposits, and do not properly belong to what Bettman calls iodiopathic fibrinous bronchitis. Late in the course of tuberculosis, casts of the bronchi may be expectorated. Hot vapor has been known to produce fibrinous casts. Chemical irritants, such as ammonia, have been known to produce a similar membrane in the trachea and bronchi, but are not expectorated.

The use of lactic acid for tuberculosis of the

*I demonstrated one of these casts before the Brooklyn Medical Society at its May meeting, 1903.

larynx has been said to produce ribbon-shaped mucoid shreds of the bronchi (Hoffmann).

The sputum may be greenish, as in Escherich's case of fibrinous bronchitis. Greenish sputum is exceptional, and is more often seen in the pneumonia of the aged.

The casts consist miscroscopically of a hyaline basement membrane, and are of lamellated structure, the individual lamellæ being arranged either concentrically or in irregular layers (Eichhorst). Mononuclear leucocytes are common with few red blood cells. Blood pigment (hæmatoidin crystals, Austin Flint) has been seen. Charcot-Leyden crystals and Curschmann's spirals have also been seen. Vintras failed to find Charcot crystals in his case. I have seen hæmatoidin crystals, but they are by no means so common as in abscess of the lung.

Eppinger, Huchard and Claisse, Herzog and Nachod found the bulk of the casts to be made up of fibrin, while Klein and Habel found chiefly mucus, or rather mucin. Degenerated epithileal cells are frequently seen, with fatty matter and granular detritus. Schmidt found in his case hyaline blood-cylinders, "corpora lecithinoidea," or "lecithinoid cylinders" (quoted by Hoffmann). The treatment consists in the early administration of creosote and cod-liver oil. Creosote seems to cut short the attacks, improve the nutrition of the patient, and lessen, in a great measure, the tendency to tuberculosis, which is most to be feared

Thus tuberculosis was found in ten out of twenty-one autopsies collected by Model from Bäumler's clinic. In the chronic form of fibrinous bronchitis the danger lies, first, from tuberculous complication, and, secondly, from an extension of the membrane to the air cells—fibrinous pneumonia.

In the acute form death from suffocation is more to be feared than in the chronic variety.

In both class of cases oxygen is of service to relieve the dyspnœa.

I would recommend emetics for this purpose, and inhalation of lime water or steam to loosen the membrane. Alkaline (bicarbonate of soda) spray may be used. The fewer cough mixtures given in this disease the better.

I have found a codeine tablet of ¼ to ½ grain given occasionally of some benefit.

A nutritious diet and fresh air are important.

It is remarkable that this disease should occur chiefly in males rather than in females, and it has been known to occur in several members of the same family.

As before stated, I have found the iodide of potassium and mercury useless, but nevertheless, believe that syphilis stands in a certain percentage of cases in etiological relation with this disease. In acute cases Biermer advises mercury.

Not all diseases or morbid states are due to bacteria alone. The bronchi, like the mouth, although to a less extent, contain, even under ordinary conditions, a great variety of microorganisms.

In diseased processes of the respiratory tract, as in this disease, varied microorganisms, which ordinarily find their habitat in the mouth and bronchi, become more abundant. It is often not the finding of a given microorganism which is important, but the number of germs. Thus different bacteria may stand in etiological relation to a given morbid process. I have seen protozoa in noma and in thrush in addition to the usual fungus of this disease, Oidium albicans, while at the same time other bacteria multiply in numbers.

The aphthous stomatitis (foot-and-mouth disease), in which inflammation and vesiculation occur in the mouth, may have as a prolific cause the streptococcus of Klein, or the micrococcus of Cnyrim and Libberitz, or other organism, yet I feel that these are not the only cause of a similar morbid state with gastric disturbance, which I believe may be due to chemical irritants, of which the wonderful and complex tar colors and allied dye-stuffs so widely and indiscrimately used in the arts and foodstuffs serve as a cause, as it does of cases of alleged ptomain poisoning.

The wonderful and complex chemical composition of many of these series of tar colors, as well as physiological experiments, will refute the idea that arsenic alone is the deleterious agent, althoug potent factor.

I ask your indulgence for this digression, and feel that in seeking the origin of disease, whether it be fibrinous bronchitis or some others, much is yet to be learned.

In conclusion, I reiterate my belief that creosote given during the attacks, and carefully during the intervals, is the proper drug for this disease.

That chronic fibrinous bronchitis *per se* is not tuberculosis, is proven by the fact that tubercle bacilli are absent in the sputum.

The great value of this treatment lies before their presence becomes manifest, but even afterward it is not contraindicated.

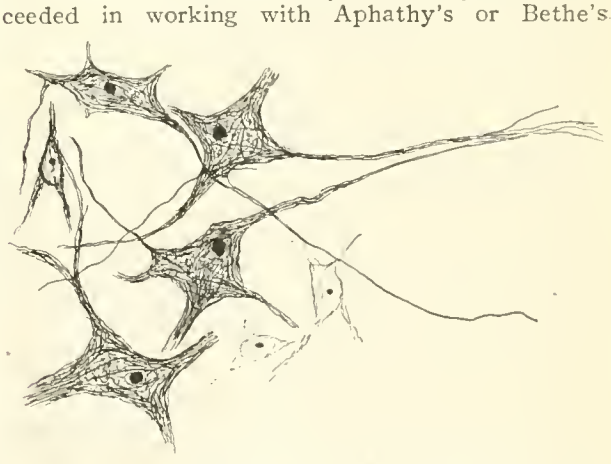
300 South Fourth Street.

FIBRILS AND GANGLION-CELLS.

By V. BIART, M.D.,
CAPTAIN U. S. ARMY, RETIRED.

The investigations which have been made during the last years regarding the structure of the ganglion-cells have, as is well known, dealt very much with the question, whether, besides the Nissl granules, there really exists fibrils passing through the cell-body from one cell to another. There has been much written about an intrinsic network within and around the cell, and between the cells.

Aphathy's and Bethe's work in this field are well-known, but I dare say not many have succeeded in working with Aphathy's or Bethe's



complicated methods. A new method has, however, been recently published by S. Ramóny Cajal of Madrid, which recommends itself by its great simplicity, as well as by its satisfactory results. Prof. L. Edinger, Director of the Senckenberg Neurological Institute, of Frankfort-on-the-Main, in whose laboratory and under whose guidance I have been working for some time past, desiring to test the efficacy of this new method, requested me to try it.

I accordingly went to work, and after a few trials had the satisfaction of obtaining most gratifying results. The simplicity of the method is apparent, when one considers that it requires no

other manipulations than the immersion of small pieces of nervous tissue in a weak solution of nitrate of silver, in which they are left for a few days at a temperature of about 95° F. and are then submitted to the reducing action of a pyrogallic acid bath. After proper dehydration they may be mounted, either in celloidin or in paraffine. The microscopical images obtained are remarkably clear and well-defined. This is especially so when the greatest contrast between the fibrils and the background has been attained, in which case the latter is exceedingly light and transparent, whereas the cells and the fibrils appear as delicate structures of either black or dark-brown color.

The beauty of this method is well exemplified by the accompanying illustration: It represents cells, etc., of the anterior horn of the cord of a newborn rat. The drawing was made by Dr. Kurt Goldstein, assistant at the institute, and is a perfectly exact copy of the microscopical image, even in its very finest details.

I should like to insist upon the fact, that all the fibrils shown by this perfect method are lying within the cells or their processes, and that there is no indication of an intercellular network, as claimed by Nissl, who lays especial stress on such an one.

According to Nissl, not the intracellular network shown in this illustration, but an hypothetical intercellular network forms the basis of the performance of the functions of the nervous system.

It is certainly very interesting that, even in this complete preparation, Nissl's network is not apparent.

Frankfort-on-the-Main, Germany.

A Chinese Physician.—The contrast between precept and practice in the Far East is sometimes puzzling to the Western mind. We have heard much of late concerning the barbarity of Chinese medicine, but the following account by an old Buddhist of an ideal medical man—most probably a Chinaman—should give pause to all such as believe the Chinese physicians to be little better than savage medicine-men. Our quotation is from Colonel Yule's notes on Marco Polo's "Voyages": "In my own town," says the Buddhist writer cited by Colonel Yule, "there lived a physician by name Chang-yang-ming. He was a man who never took payment for his treatment from anyone who was poor; nay, he would often make presents to such persons of money or corn to lighten their lot. If a rich man would have his advice, and paid him a fee, he never looked to see whether it was much or little. If a patient lay so dangerously ill that Yang-ming despaired of his recovery, he would still give him good medicine to comfort his heart, but never took payment for it. I knew this man for many a year, and I never heard the word *money* pass his lips. One day a fire broke out in the town and laid the whole of the houses in ashes, only the house of the physician was spared." Colonel Yule comments thus on this passage: "Of such as this physician the apostle said: "Of a truth I perceive that God is no respecter of persons, but in every nation he that feareth Him and worketh righteousness, is accepted with Him."—*The Lancet.*

Albuminuria in the Apparently Healthy.—Samuel West believes that under ordinary conditions physiological albuminuria does not occur, and when it does it is a transudation, not a secretion. The greatest importance is to be attached to the state of nutrition of the walls of the capillaries, and also to the presence or absence of high, arterial tension. Cases under consideration may be divided into three groups: (1) post-renal, or accidental, due to the contamination of the urine from the genito-urinary tract; (2) renal (*a*) with obvious cause, as kidney disease, (*b*) without obvious cause; (3) pre-renal (*a*) with obvious cause as in fevers or heart disease, (*b*) with no obvious cause. With regard to the post-renal class of cases a tiny calculus in the kidney may lead to a transient albuminuria or hæmaturia, the condition completely clearing up with the passage of the stone. Temporary albuminuria may also be due to the passage of oxalic acid gravel. It is also said that the strongly acid urine of acute gout may likewise give rise to the same condition. Many different names have been given to this form of albuminuria. Its importance and significance vary with age. In school children the practical question is whether the school life should be interfered with. The writer believes that each case should be judged upon its own merits and that continuance at school under medical supervision is the best course to pursue. The gravity of the condition increases almost *pari passu* with every year. The chief point in the whole question lies in the difficulty of excluding latent disease of the kidneys, especially granular kidney. In regard to life insurance, it is advisable to reject all cases of albuminuria above the age of forty, to load heavily those between thirty-five and forty, to add considerably between the ages of twenty-five and thirty, and to postpone and watch those cases occurring between eighteen and twenty-five. If arterial thickening is present at the same time one should reject at all ages. Albuminuria is never physiological but always pathological, though not necessarily renal.—*Medical Press and Circular.*

Some Aspects of Obesity.—Leonard Williams declares that obesity is not only not a disease *per se*, but occasionally it is not even, strictly speaking, pathological, inasmuch as its presence is apparently essential to the ordinary physiological working of certain individuals. In the commoner forms, obesity is due to a want of balance between intake and output. Too much food is eaten or too little is oxidized. The ingested material may be excessive in quantity. This is frequent in the case of those who have been athletic in youth. That class of women patients, too, who think they need "supporting" habitually takes more food than can be assimilated. The practice of drinking fluid with meals is another cause of the ingestion of too much food. This fluid not only seems to increase the appetite, but by enabling the food to pass more rapidly out of the stomach than it would otherwise do, it makes it possible for the patient to eat more. Insufficient mastication leads to the ingestion of a great deal of unnecessary food. Excess may be a matter of quality. The quantity itself may be moderate enough, but the excess may reveal itself in the relative quantities of fat-forming or fat-saving principles. The starches, sugars, fats, and alcohol, are most readily converted into adipose tissue. As to the oxidation of food, the chief agent in effecting this is muscular exercise. Ordinary obesity probably never occurs where circumstances allow this agent full play. When obesity is already established, there are substitutes for ordinary exercise which may be used, such as massage, electricity, Swedish movements, and Zander exercises. The nervous system plays a part in the oxidation of food. Mental anxiety may give rise to an extreme degree of emaciation. The obese patient must have mental and physical energy forced upon him. The writer believes that hot baths for ablutionary purposes by the young and healthy are most undesirable, except when they are immediately followed by cold affusion and vigorous toweling. The prevalent vice of overclothing is still more important. The wearer of flannel under-garments, as far as his skin is concerned, lives in a moist climate—relaxing in its effects. The activities of skin and lungs, bowels and kidneys, are very important. Mineral waters, in so far as they are helpful, are so in virtue of their effects upon the bowels and kidneys when taken internally, and upon the skin when administered in baths. The writer concludes by speaking of the use of thyroid extract in obesity. Its use is by no means unattended by danger.—*The Practitioner.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51, FIFTH AVENUE.

New York, August 6, 1904.

AN EDITORIAL CHANGE.

IT is with deep regret that we have to announce the resignation by Dr. George F. Shrady of the editorship of the MEDICAL RECORD after nearly forty years of continuous service. Dr. Shrady has had editorial control of this journal from its foundation, and it is to his initiative and executive talent that the MEDICAL RECORD owes the position it holds to-day in American medical journalism. The journal was founded thirty-eight years ago, with Dr. Shrady as sole editor, and his name has been on the title-page of sixty-five consecutive volumes—a record of continuous editorial management exceeded, we believe, only by that of the Wakleys and *The Lancet*.

The first line of type of the first number of this journal was set by Dr. Shrady, the first leader was penned by him, and from March 1, 1866, to June 25, 1904, it has been his policy that controlled the editorial pages. During that time the paper has grown from a semimonthly of twenty-four pages in each issue to a weekly of over 2,000 pages a year. It has chronicled some of the greatest triumphs that medicine has had in all the ages, and in its pages may be read the history of discoveries which have raised the study of disease almost to the level of an exact science. It has witnessed, too, and chronicled, and taken part in some stirring episodes of medical politics, through all of which it was guided by the courageous conscience of the editor who feared not to speak up for what he believed to be the right—and to him has come the satisfaction of seeing, before laying down his burden, the acceptance by the medical profession of the entire country of the principles for which he so earnestly contended.

The change in editorial management of the MEDICAL RECORD involves no radical change in policy or methods, for the former associate editor, who now becomes editor in chief, assisted Dr. Shrady in the conduct of the journal for some twenty years, and for the past several years a great part of the editorial work has been under his sole direction. The personnel of the editorial staff remains as before.

The friends of the MEDICAL RECORD and of Dr. Shrady will unite with us in making grateful acknowledgement of what the retiring editor has done, not only for this journal but also for medical journalism in general. They will also join with us in the expression of cordial good wishes and of the hope that he may have still many years in the enjoyment of a well-earned rest from his unselfish labors in the cause of medical learning.

PERFORATING WOUNDS OF NERVE TRUNKS.

IN the Boer war, according to Major S. F. Freyer (*Journal of the Royal Army Medical Corps*), lesions of nerve trunks seemed the commonest complications of Mauser bullet wounds. These wounds closed usually by first intention, but the nerve repair at the time of healing was notably imperfect. The most striking thing, however, was the incompleteness of the paralysis (sensory or motor) below the lesion. In not one aseptically healed wound did Freyer see complete paralysis; and though others have met with complete division of nerves, he believes that will prove extremely rare in Mauser wounds. He gives in detail three cases in which on operation nerve trunks were actually seen to show a central perforation, though the diameter of the bullet was much greater than that of the nerve trunk. In the first case the wound was a puncture of the musculospiral nerve only just large enough for the end of an ordinary pocket-case probe to drop through; in the second, a central perforation of the median, large enough to admit a large probe; in the third, a slit-like aperture of the median which left three-quarters of the nerve intact. This lesion is, the author remarks, evidently a new one in military surgery. It was undoubtedly one of the chief causes for invaliding home. During the few weeks that the wounded were under observation in South Africa, little or no improvement took place in nerve lesions generally, but the degree of recovery ultimately attained in these perforated lesions was surprising. Thus in two cases there was perfect recovery, and another case showed, four years afterward, great improvement, but there was some wasting of the small muscles, and the fist could not be clenched. It can only be surmised that the nerve flattens out in advance of the bullet on the impact of the latter, or that the conical shape of the Mauser splits up the nerve trunk. That it is not, however, special to the Mauser, is shown by the fact that the wound in one of the cases was from an ordinary service revolver bullet with blunt leaden nose.

As regarded treatment, it was considered sufficient to replace the nerve in its bed, and the results seem to have justified this course. The inference drawn by the author is that undoubtedly in partial lesion of a nerve trunk when the wound has healed by the first intention, any operation on the nerve is unnecessary. The only apparent exceptions arise in complicated cases, as when a bone has been fractured, and the nerve is imbedded in callus. True, all bullet wounds involve a string of cicatricial tissue, but with Mauser wounds this is very fine, and we know clinically that this sort of cicatrix seems not to interfere materially with the growth of the young nerve fibers, and until the results of nerve suturing are more definite and certain, it is inadvisable to interfere in these partial breaches of continuity by operation.

As regards the time of restoration of function, the author's experience on medical boards has shown him that years and not months must be allowed for complete restoration, many such cases showing little improvement in six months, though eventually, to all appearances, recovering entirely.

In the cases described there was no naked-eye

evidence of any neuritis, and the author believes that this condition is for the most part confined to septic wounds. In nerve wounds the whole prognosis turns, he thinks, on the possibility of obtaining primary union in the bullet track, the importance of which cannot be exaggerated. In South Africa this result was attained in the immense majority of cases, it being astonishing how readily the Mauser wounds closed and scabbed over when not interfered with.

The causes of this may prove instructive in regard to wounds in general. It is not that the "first dressing" has not come in for its full share of credit. Indeed, there is just a danger of attributing more than a due share of the success to asepticism, or some one or other of the antiseptic systems. Or rather, perhaps, the danger lies in neglecting the physical factors acting upon and common to all wounds, and which are preeminent in the healing process. The results of Preobrajensky (*Annales de l'Institut Pasteur*, 1897) would well repay the attention they have not excited. He demonstrated conclusively the overwhelming importance of the physical in comparison with the chemical characters of a dressing, showing that the forces of evaporation, osmosis, and capillarity, intelligently assisted by an absorbent dressing, can set up such a fluid current from the depths of the wound to the surface, that ordinary infection is practically impossible, and even deliberate infection by the anthrax bacillus somewhat difficult. In Mauser wounds, as in all well-planned operation wounds, the surfaces fall together in the depths, and there is a constant current outward through the little fluid between the raw surface. Preobrajensky also found that when a sufficient "molecular adhesion" existed between the dressing and the fluid in the wound, the efficiency of the dressing depended on its permeability and capacity for absorption. For the latter nothing stands higher than gauze, so that, hermetically sealed wounds apart, gauze (or a gauze substitute) is the only thing common to all aseptic, and antiseptic systems. And in Preobrajensky's opinion, this reconciles the results attained by successful surgeons whose systems seem to differ widely and more or less antagonistically.

Ricinus and Pawpaw Plants as Deterrents to Mosquitos.

From time to time, certain plants have been advertised as obnoxious to mosquitos. In fact it has been confidently alleged of some that not only would mosquitos shun them, but they were so deadly to these insects, that in those districts in which such members of the vegetable world existed mosquitos would be conspicuous by their absence. Upon close investigation the majority of these statements have been discredited, and have proved to be but idle tales.

For example, Groom, in the *Journal of Tropical Medicine*, July 15, 1903, asserted that the pawpaw plant (Carica papaya) had so deterrent an influence upon mosquitos, that they would not venture into its neighborhood. Castor plants are commonly credited with a similar action. In order to test this reputed effect, MM. Edmond and Etienne Sergent, as related in the "Comptes rendus de la Société de Biologie," 1903, p. 1357, placed a pawpaw plant in the middle of a mosquito net of oblong shape in such a way that mosquitos would be compelled to pass it in traveling from one end to the other. At the end of the net nearest the window were placed a dish of water and a raisin, of which mosquitos are inordinately fond. At the opposite end four female Anopheles maculipennis and four female Culex pipiens were introduced. In a short time one anopheles and one culex had reached the far end of the net, and were resting on the leaves of the pawpaw. The insects were confined in the net for one week, during which time one anopheles and one culex died. From experiments of a like nature with the ricinus plant, exactly similar results were obtained. Thus it will be observed that neither the pawpaw nor the ricinus exerted any influence upon mosquitos.

C. P. Handson, writing in the *Journal of the British Royal Medical Corps* for May, says that his observation has led him to conclude that the ricinus actually attracts mosquitos. The same may be said of the eucalyptus plant, which has the reputation of being inimical to mosquitos.

Indeed, the result of investigations would seem to show that not only are these trees no safeguard against mosquitos, but are in truth harmful, as they harbor them during the day.

The Battle for Health in the Tropics.

Major Ronald Ross, in an address recently delivered before the Northumberland and Durham Medical Society, complained of the difficulties with which he had to contend in endeavoring to battle with the malaria-bearing mosquitos.

The great mass of the people are everywhere notoriously skeptical with regard to matters beyond their ken, and if all the moot points of a new but well-established theory are not cleared up to their entire satisfaction, its validity will be doubted, despite the fact that the said theory has been universally accepted by scientific men. This human failing has been especially evident so far as the relation between mosquitos and malaria is concerned. The belief that the disease originates and spreads from marshes and swampy lands has been too long held to die easily. Major Ross points out that this skepticism on the part of the public is of great importance as regards the prevention of malaria; because it shows us how little we can trust the population at large to take preventive measures against the spread of disease. Therefore, he is of the opinion that our only hope for the extirpation of malaria and other important tropical diseases on a large scale lies in government action. In tropical climates, in those places in which malaria is prevalent, drainage, whenever feasible, is the best course to pursue in order to destroy the disease-bearing insects. Of course in many instances "the game is not worth the candle." But in all tropical towns a scrupulous surface drainage should be undertaken, thereby removing the small puddles in which the anopheles chiefly breed. It will be undoubtedly a long time ere malaria is extirpated, although there is reason to hope that such a result may eventually come to pass. The sooner, however, that the general public take an intelligent interest in the matter and give active coöperation the more quickly will that happy day arrive.

The Murder Habit.

Statistics of murders, which have just been compiled in Italy, show that while in France the annual rate is one murder to every one hundred thousand inhabitants, in northern Italy it is four, in the middle provinces twenty-four, and in

the southern provinces, including Naples and Sicily, it is thirty. Last year the Cook County (Illinois) Coroner held inquests in 118 cases of homicide, of which only 11 were reported by him as justifiable. This is at the rate of about six for every one hundred thousand of the population. Chicago can hardly take pride in the fact that her murder record is five times better than that of Naples and Sicily, for she has to admit that it is six times worse than that of France. Probably the local record for the current year will be better than that of last year, for the numerous instances of severe penalties inflicted by juries during the first six months of the year cannot fail to have their effect. Nevertheless, the need of improvement will still be marked, and improvement can come only as a community places a higher value on human life and insists that all public officials take the most vigorous methods to bring all murderers to justice.

News of the Week.

The Registration of Births.—Dr. Thomas Darlington, Commissioner of Health of the city of New York, has issued a circular letter to the physicians of the city directing attention to their moral and legal responsibility relative to the registration of births. The failure of the physician to comply with the law requiring him to register births is attended, the commissioner says, with serious consequence to the child, who is deprived of the opportunity in many cases to help his parents and earn his own livelihood at a time when he is willing and able so to do; for upon the filing of a birth certificate by the physician in attendance at the time of birth may depend the admission of the child to the public school at the proper age, and his ability to obtain employment on arriving at the age of fourteen, provided he is unable to furnish other proofs of age. The new Labor Law, which took effect October 1, 1903, requires the parents of the child to furnish documentary proof before the Board of Health is allowed to issue an employment certificate. In the case of native-born children, the only proof available, besides the birth certificate, consists of religious records—baptism, confirmation, circumcision, etc. But when the parents stand outside of any religious communion, or when they have neglected the ceremonies attached to their belief, there remains no other proof than the record of birth. Physicians failing to comply with the law thus lay upon themselves a serious moral responsibility, besides rendering themselves liable to a fine of one hundred dollars.

The National Association for the Study and Prevention of Tuberculosis has secured an office in the United Charities building at Twenty-second Street and Fourth Avenue. The work of the association will be mainly one of education. There is no intention of founding any sanatorium or dispensary for the treatment of the disease. It is not likely that a laboratory even will be instituted at first, although that may be done later. The work planned for the present is the collection and dissemination of information of every sort touching the disease. Statistics will be collected and pressed on the attention of municipal bodies and institutions in order to get them to make scientific warfare against the spread of the infection. The formation of local associations and committees will also be urged and assisted in every possible way. One of the first definite enterprises will be the publication of a tuberculosis directory, containing, among other things, information regarding the one hundred and twenty-five hospitals and sanatoria in this country and Canada specially equipped for the treatment of tuberculosis.

Philadelphia Free from Smallpox.—According to a statement issued by Dr. Edward Martin, Director of the Department of Public Health and Charities, the city of Philadelphia is, for the first time in three years, free from smallpox. The epidemic has cost thousands of lives and millions of dollars. It was due to some irregularity in the quality, efficiency, or purity of the vaccine and to widespread neglect of vaccination. To insure the discovery of isolated or imported cases and to prevent any possible spread of the disease, house-to-house inspection will be made by the medical inspectors, and those unprotected will be vaccinated. Especial stress is laid upon the vaccination of little children.

Typhoid Fever in Cincinnati.—The report of the Health Department for the week ending July 23 shows a decrease in the number of all cases of infectious diseases except typhoid fever. Here there is a marked increase over the corresponding week of last year. Then there were 16 new cases with 5 deaths against 69 new cases and 11 deaths this year.

Allegations of Cruelty against Nurses of the Insane.—After examining fifty employees of the Northern Hospital for the Insane, the Illinois State Board of Charities voted that the charges of abuse and cruelty preferred by the Elgin Trades Council in a recent letter to Governor Yates were baseless. The board is charged, however, with not giving the members of the Trades Council, who have made affidavit to special cases of cruelty, proper opportunity to appear. The board had what purported to be the original charges, and made an investigation among the employees of the asylum to discover if any attendant, nurse, physician, or other official had committed any of the brutal deeds set forth in the accusing document, and each of the witnesses asserted there could be no possible premises upon which to build tales of inhumanity.

A New Medical School in China.—Recently several foreign missionary societies in this country and England agreed to establish jointly a school of high rank in China for the instruction of natives in the principles of modern medicine and surgery. In accordance with the scheme a medical college is now under construction. The cost is estimated at $50,000. Toward this the Dowager Empress has contributed about $6,000. Subscriptions are now being sought from high Chinese officials, who are expected to follow the example of the Empress. There will be a five-year course, and the school will have authority to confer the degree of doctor of medicine upon students who complete this course and pass the examination successfully. The training will be regardless of creed, but the bulk of the students at first will naturally be Christians.

Laboratory of the Rockefeller Institute.—Plans have been filed for the laboratory of the Rockefeller Institute of Medical Research, which is to be built on Exterior street, east of Avenue A. It is to be a five-story edifice, 136 feet front; with a pilastered façade of limestone and ornamental brick. The upper stories are to be furnished as general and special laboratories and research rooms, and the roof will have houses for the animals. The building will also have an auditorium hall and a library and study on the first floor. An annex will contain a two-story building for the animals, and a power-house.

Medical Society of the Missouri Valley.—The seventeenth annual meeting of this association will be held Thursday and Friday, August 25 and 26, at Council Bluffs, Iowa, under the presidency of Dr. A. D. Wilkinson of Lincoln, Neb. The adoption of a new constitution and by-laws, placing this society in line with the American Medical Associa-

tion, which is to be voted upon, will, if effected, make this one of the most important meetings in its history. The secretary of the society is Dr. Charles Wood Fassett of St. Joseph, Mo.

The American Neurological Association will hold its next annual meeting at St. Louis on September 15, 16, and 17, 1904, under the presidency of Dr. James W. Putnam of Boston. The sessions will be held at the Planters Hotel instead of at the Inside Inn, as originally planned; they will last from 9 A.M. to 1 P.M. daily. A general invitation to attend is extended to the medical profession. The secretary of the association, is Dr. Graeme M. Hammond, 58 West Forty-fifth Street, New York. The chairman of the Committee of Arrangements is Dr. Frank R. Fry of St. Louis.

Increase in Suicide in New York.—The records of the Police Department and the Health Board show an increase in the number of suicides in this city. It is estimated that the number of suicides during the first six months of the year was over 450, while 264 persons made unsuccessful attempts to take their own lives. It is reckoned that this year's total of suicides will be in excess of 900, as against 806 last year, 772 in 1902, 678 in 1901, and 743 in 1900. Out of last year's aggregate of 806 suicides, about 35 per cent. were native born, 26 per cent. were German, and less than 7 per cent. were Irish. Russia furnished about 5 per cent. of the total, England 3 per cent., and Austria-Hungary something less than 5 per cent.

Charters of Medical Colleges in Danger.—Dr. Henry Beates, President of the Pennsylvania Board of Medical Examiners, is quoted as stating that the charters of several medical colleges may be revoked because the graduates of these institutions are not sufficiently equipped for the proper practice of their profession. The statement is based upon the results of recent examinations of applicants for license to practise medicine in the State of Pennsylvania. The difficulty is attributed to insufficient preliminary education and defective methods of medical teaching.

Effort to Compel a Medical Board to Issue License.—Dr. S. DeMeyer of St. Louis has filed an application with the Circuit Court in that city asking that a writ of mandamus be issued against the State Board of Medical Examiners to compel that body to issue him a license as a regular practising physician. His application states that after the board had evoked his license he appeared at a meeting on May 3 last and asked that the action be reconsidered, but his request was denied. With his application Dr. DeMeyer files an exhibit purporting to be a resolution passed by the board, which states, among other reasons for revoking the license, that he changed the face of the license by inserting "De" before "Meyer" in his name.

Low Death Rate in Philadelphia.—For the week ended July 30 there were reported to the Philadelphia Bureau of Health 434 deaths, as compared with 482 for the previous week and 485 for the corresponding week of the preceding year. The largest number of deaths due to one cause was 84, namely gastroenteritis in children under the age of two years. Fifty-one deaths were due to pulmonary tuberculosis, and forty to diseases of the heart.

The Medical Society of the Woman's Hospital of Philadelphia was organized June 30 at a meeting of the hospital staff. Dr. Mary W. Griscom was elected president for the ensuing year.

Dr. Charles Norris of New York has been appointed director of the pathological laboratories in the department of Bellevue and allied hospitals, said appointment to date from October 1, 1904.

Illness of the Kaiser's Son.—Prince Oscar, the youngest son of the German Emperor, is said to be suffering from an affection of the throat, probably tuberculous in nature. He is now at Interlaken, where he was sent by his father, acting upon the advice of Professor Gerhardt.

Bequest to Hospital.—By the will of the late Mrs. Marie L. Gage of Philadelphia the sum of $5,000 is bequeathed to the Presbyterian Hospital in memory of her husband.

Changes in Medical Faculties.—Profs. Orville E. Brown, Elias P. Lyon, and Chas. H. Neilson, of the Department of Physiology of the University of Chicago, have resigned to accept similar positions on the Faculty of the University of St. Louis.

Will of Dr. N. S. Davis.—The will of the late Dr. N. S. Davis disposes of an estate valued at $39,000, of which $25,000 is real estate. The homestead is bequeathed to his widow, his library to his son, and a perpetual scholarship in Northwestern University to his grandson, Frank H. Davis.

Dedication of Kewanee Hospital.—The new St. Francis Hospital, Kewanee (Illinois), which has been erected at a cost of $100,000, was dedicated on July 24 with impressive ceremonies. The dedicatory address was delivered by Bishop Spalding.

Opening of a Tuberculosis Hospital.—The new hospital for the treatment of consumptives at Dunning was turned over to the officials recently, and a little later all the patients in the old building were transferred. The new hospital consists of five cottages, and will accommodate one hundred and sixty patients. The old building is to be used as a hospital for the sick insane.

Work of a Nurse Association.—The report of the Visiting Nurse Association of Chicago for the month of July shows that 798 patients were attended and 3,679 visits made. The principal cases treated were consumption, typhoid fever, and children's diseases. The work of the association is greatly hampered by lack of funds, more nurses being needed at once.

New Building for Cripples.—Mrs. R. H. McElwee of Lake Forest (Illinois) has donated a new building to the Home for Destitute Crippled Children. The gift will be in the form of an extension to the present structure, and will cost from $30,000 to $40,000. The work of construction will begin soon. The institution as it stands affords accommodation for thirty-five or forty crippled little ones, but even with that limited number its wards are overcrowded. The new wing will house eighty more.

Manufacture of Liquid Air.—Demonstrations in the manufacture of liquid air will be given at regular intervals in the Department of Liberal Arts at the World's Fair. The experiments will be conducted by the British Royal Commission in a building erected for that purpose and lectures will be given twice a week. The plant is a reproduction of the one used by Prof. James Dewar in his extreme low temperature researches at the Royal Institute, London.

Obituary Notes.—Dr. H. S. TORRANCE of Cripple Creek, Colo., was killed recently in a railway accident near Cameron, Colo. He was born in 1869 and was graduated from the Medical Department of the University of Pennsylvania in the class of 1891. He was a member of the Colorado State Board of Health, to which he was appointed in March, 1902.

Dr. GEORGE V. WENNER of Milford, N. J., died July 19. He was forty years of age and was a graduate of the Medico-Chirurgical College of Philadelphia in the class of 1896.

Dr. D. H. BADGELY died at his home near Cin-

cinnati on July 21, at the age of seventy-eight years. He was a pioneer and one of the early settlers in the vicinity of Cincinnati.

Dr. Henry M. Wetherill died in Philadelphia on July 28 at the age of fifty-two years. He was a graduate of the Philadelphia College of Pharmacy and of the Medical Department of the University of Pennsylvania in the class of 1877. He subsequently became a resident physician in the Philadelphia Hospital and the Pennsylvania Hospital. He had for several years been secretary of the State Board of Lunacy and Charity.

Dr. John W. Morrison died at Cochranville, Pa., on July 26 at the age of ninety-three years. He had been engaged in the practice of medicine for sixty-five years, was Surveyor of the Port of Philadelphia under Professor Buchanan, and the only surviving member of the Thirty-third Congress. He was president of the Parkesburg National Bank.

Dr. Albert P. Fulkerson died at his home in Lexington, Mo., on July 28. He was born in Lee County, Virginia, in April, 1836, and came to Missouri in 1855. During the Civil War he served as surgeon in Parson's Brigade of the Confederate Army. His wife, two sons, and a daughter survive him.

Dr. Richardson B. Okie died at Berwyn, Pa., on July 30, at the age of fifty-four years. He was graduated from the Medical Deparment of the University of Pennsylvania in 1870.

THE BRITISH MEDICAL ASSOCIATION.

The seventy-second annual meeting of the British Medical Association was held at Oxford from Tuesday to Friday of last week, July 26 to 29. Through the courtesy of the editor of the *British Medical Journal* we are enabled to present abstracts of the general addresses in advance of the special report prepared for us under the direction of our London correspondent.

The Growth and Development of the Oxford Medical School.—This was the subject chosen by the president, Dr. William Collier of Oxford. He reviewed the history of the Oxford medical school, in which great changes had occurred since the last visit of the British Medical Association to Oxford, in 1868. The members of the association took a keen interest in the school and took active measures to bring about many changes. In 1880, when the association met at Cambridge, Sir George Humphry, the then president, urged that the department of medicine be given its full share of attention. He pointed out that originally the Faculty of Medicine had been placed on a par with those of Divinity and Law, and the provisions for teaching and graduating in all these faculties had been made alike. The College of Physicians in London, founded by the influence of Linacre, with the privilege of licensing practitioners throughout the kingdom, became in time the succesful rival of the old Universities of Oxford and Cambridge. As the influenee of the London College increased, little was left to the universities beyond the function of giving a preliminary training to the few who could avail themselves of it. In other countries the only avenues to medicine are the universities. In 1878 an anonymous letter was published complaining bitterly of the way in which the study of medicine was entirely overlooked at Oxford, and the controversy thus started was carried on with vigor for months. Some were very anxious to establish a complete medical school. The British Medical Association took up the question and adopted a memorial in which was urged the immediate constitution of a thorough medical curriculum, at least in the subjects of anatomy, physiology, general pathology, materia medica, clinical medicine and surgery for beginners, and state medicine, including medical jurisprudence and public health. This memorial was signed by upward of 2,000 members, and a little later another petition of similar import, signed by a different body of men, many of them London teachers, was drawn up. In November, 1882, Burdon Sanderson was appointed to the Chair of Human Physiology and Histology at Oxford, and this was the first step toward the establishment of medical education in Oxford on modern lines. Laboratories and lecture-rooms were then built for the professor of physiology. In 1885 the Faculty of Medicine was re-created, and Arthur Thomson was appointed Lecturer in Anatomy. In a year or two the lectureship was converted into a professorship. In 1886 a statute was passed by which students in natural science were exempted from the first public examination in classics known as Moderations. This enabled medical students to devote their first year at Oxford to the study of preliminary subjects in natural science. In 1891 Henry Acland inaugurated a new department in bacteriology, and in 1895 Sir John Burdon Sanderson succeeded Henry Acland in the Regius Professorship, Gotch taking Sanderson's chair. In 1896 Jerome was appointed Lecturer in Pharmacology and Materia Medica. In 1898 a decree was passed empowering the university to spend £7,500 in erecting new laboratories and lecture-rooms for the study of botany and comparative anatomy. In 1901 the new pathological laboratory was opened. Various friends of the university gave generous donations, and the Drapers Company presented the magnificent medical library. An excellent eye hospital now exists in the city, due to the efforts of Mr. Doyne. The present condition of the university shows how generously the former requests of the association have been complied with. The orator then spoke of the many brilliant names that have been associated with the university and of the influence of the school. John Radcliffe, he said was, of all, the greatest benefactor. He was born in 1650 and died in 1714. During his life he gave largely to his old college and to several charities, and at his death he left by will his Yorkshire estate to the Masters and Fellows of University College forever, to be held in trust for the founding of two Radcliffe travelling fellowships, the overplus being paid for the purpose of buying perpetual advowsons for the college. In addition he left £5,000 for the enlargment of the college and £40,000 for the building of a medical library. With money derived from his estates, two other buildings were erected in this city by his trustees, the Radcliffe Infirmary and the Radcliffe Astronomical Observatory, and money was further granted toward the building of the College of Physicians in London. The Radcliffe Library in Radcliffe Square, completed in 1747, is one of the most conspicuous buildings in the city. It was in this building that the first meeting at Oxford was held in 1835, on the third anniversary of the organization of the British Medical Association. Sydenham, Matthew Lee, Lord Litchfield, and George Aldrich were other noteworthy benefactors of the Oxford School in times past. In conclusion, Dr. Collier recalled the previous meetings of the association in Oxford, in 1835, 1852, and 1868.

The Sanitary Needs of the United Kingdom.—Sir William Selby Church took as the title of his address in medicine "Our Sanitary Needs, with Special Reference to the National Health." He referred briefly to the position in which medical knowledge stood in 1868, the last time that the British Medical Association met in Oxford. Up to that time the conceptions of the causes of morbid changes in the

body had not undergone any great modification from the views held by the originators of pathology—Morgagni, Hunter, Baillie, Carswell, and others. Knowledge of the infective processes leading to inflammation and suppuration did not really exist at that time. As to the specific fevers, their symptoms and course as well as the circumstances under which they occur had been thoroughly recognized and worked out, although the true nature of the specific poisons on which they depend was not known. It was in the year before the Oxford meeting that Lister at Dublin read his paper on the "Antiseptic Principle in the Practice of Surgery," founded on the results of his treatment of compound fractures, abscesses, and wounds, during the preceding three years. The infectivity of tuberculous matter began to be generally recognized at this time. But it was a wide gulf that separated the medicine of the present day from that of our immediate predecessors. William Gull, in speaking of infectious diseases, said "that they spread by emanations from the sick must have been long known, and that such emanations are of a solid nature we may infer from the fact that they may be dried and conveyed from place to place, but in what state, whether as amorphous material or as germs, we know no more to-day than was known a thousand years ago." Now we are acquainted with the specific organisms which are the *causa causans* of many of the febrile diseases, and can safely assume that the others in which we have not yet discovered the microorganisms are due to a similar agency. It was the adaptation of Pasteur's work and discoveries to Medicine, and Koch's demonstration of the bacillus of tubercle in 1882, which led to the revolution which has taken place in our conceptions of the nature and cause of many forms of disease. The writer then touched on the subject of immunization and the phenomena presented by the agglutinative, bactericidal, and hæmolytic properties of the blood serum under certain conditions. In the realm of physiology, another important step was taken when the connection between the group of symptoms called myxœdema and disease of the thyroid gland became known. The brilliant results following the administration of the thyroid gland or its extract in myxœdema raised hopes that the administration of other glandular extracts would be beneficial in those conditions in which it appeared probable that there was some defect in an internal secretion. These hopes, however, have not yet been realized. The writer then suggested that possibly the problem was not the simple absence of a normal secretion, but rather the presence of a vitiated secretion acting injuriously on the organism. Oliver had shown the remarkable effects produced on the blood pressure by the administration of small doses of creatinin, uric acid and its compounds, glycogen, xanthin, and the purin bodies contained in food. Equally active depressors of arterial pressure were found in bodies so closely allied by chemical composition to those which increase it, as creatin, hippuric acid, and hypoxanthin. Tropical medicine was next considered. The natural history of malaria and yellow fever had been slowly worked out, and the results of sanitary work in this department were very striking. That done by the authorities of the Suez Canal had already borne fruit, as shown by the fact that the attacks of malaria, in a population consisting of about 1,900 or 2,000 Europeans and 7,000 natives, have fallen from 2,089 in 1897 to 209 in 1903, and the mortality had correspondingly lessened. The expense of the work had been comparatively small. Sleeping sickness and various other tropical diseases had also more or less completely yielded up their secrets. Turning to the main subject of his address, Dr. Church said that the exact knowledge, based on scientific research and demonstration, now possessed of the cause and nature of disease had greater influence on preventive or State medicine than on clinical treatment. He believed that legislation at the present time was in advance of administration, and it was not so much fresh legislation that was needed as the simplification and codification of the existing laws. The administration of the law could not be much in advance of the knowledge and feeling of the public. Medical officers of health throughout the country, although they gave full credit to municipal and other sanitary authorities for good work which had already been done, were still fully aware of the great ignorance shown by the majority of the population concerning the principles upon which the public health depends, and of the crying need of educating the general public to the proper appreciation of the fundamental principles of sanitary science. The increase of knowledge in these lines had made it necessary for those who held important positions in connection with preventive medicine to have special preparation for their work. The orator then called attention to the necessity for supervision of the sale of food. At present the maker of foodstuffs sold under a fancy name was not obliged to submit to any authority the nature or proportion of their ingredients It was only after the article had been placed on the market that any control could be exercised by samples being taken for analysis. This gave but little indication of the suitability and value of the preparation as a food. Greater power should be placed in the hands of the health authorities. Because the necessity for sanitary regulations was so much greater in large towns, the sanitary methods appropriate there are considered by the public as the only ones, but when they were imitated in rural districts they were productive of great loss and harm to the community. Small towns often expended large sums in systems of sewers and sewerage works, which necessitated the introduction of water-works entailing another great expense. The interest of the money thus spent would in many instances have provided for the expenses incident to a proper system of scavenging. Air and light were the greatest enemies of the disease-producing microbe. But what chance had the microbe of being destroyed by these agencies in the piles of brick and mortar which were now built around central wells? Overcrowding was also one of the sins against sanitation so prevalent in this age. Whether it concerned single houses or localities, it should be more stringently dealt with; sanitary authorities, guided not by theories of disease, but by facts capable of scientific demonstration, should have the power to restrain both individuals and public bodies from perpetuating and increasing evils which were threatening the welfare and prosperity of the nation. Finally, Dr. Church urged that the association should use its influence to impress both the public and the Government with the desirability of a physical census of the nation being taken now and then, and with the necessity for the registration of the physical condition of the children on whom the future of the country and the empire depended.

Address in Surgery.—Sir William Macewen took as the first subject of his address the "Cerebral Invasion of Pathogenic and Pyogenic Organisms." He said that prior to the advent of cerebrospinal surgery in its later development, abscess of the brain was regarded solely as of a pyæmic nature, occurring by metastasis, and, owing to the aberrant manner in which abscess formed, its localization was regarded as impossible, except in the few instances in which

abscess happened to occur in parts which gave rise to functional manifestations. Some were inclined to believe that, even when abscess occurred as secondary to a primary pyogenic cranial lesion, the brain abscess was equally due to a pyæmic manifestation, and accordingly could occur at any part of the brain, distant from, and without relation to, the primary lesion. Later, however, this view was changed. It had been shown that in a large majority of cases in which abscess of the brain had formed from primary foci on the exterior of the skull, the abscess was situated in direct contiguity with the infected structures. Anatomical features generally determined the direction taken by the pyogenic organisms which passed to the brain from the primary focus. The orator stated that he had never seen a case in which brain abscess occurred by pyogenic organisms traveling by way of the internal auditory meatus. This would not be likely to occur from the anatomical features of the parts. The brain was separated from the original pyogenic focus by the whole length of the internal auditory canal. The expansion of the cerebral membranes ensheathing the nerves in the canal, however, dipped right into it. On this account leptomeningitis was set up in the canal, and from there spread over the basal membranes. Often there were collections of pus in the meshes of the pia and arachnoid, and sometimes they produced a softening and ulceration of the surface of the brain—but not cerebral abscess. He next considered tubercle of the middle ear extending to the brain with intact membrana tympani. He had personally seen ten cases of tuberculous meningitis in which the middle ear was involved without perforation of the tympanic membrane. He gave a brief history of these cases. It was possible, even on post-mortem examination, in cases in which extension to the cerebral membranes had taken place, by way of the internal ear or the sigmoid sinus, to overlook the channels of extension, on casual examination of the interior of the skull, and so the primary focus might remain undiscovered. Patients who were suffering from tubercle of the middle ear, with rupture of the tympanic membrane, were subject to secondary pyogenic invasion. This ran a rapid course, for the pyogenic organisms found abundant food for their development. There was still another way in which tubercle of the mastoid might menace life—by dissemination through the sigmoid sinus to other parts of the body. The orator noted one case of rapid illness from tubercle, resembling an acute infective disease in its rapidity and fatal termination, in which general miliary tuberculosis was found in the lungs and some of the other viscera. Both mastoids were filled with granulation tissue. There was an aperture in the right sigmoid sinus, which was in direct contact with caseating tubercle.

A Respiratory and Cardiac Reflex Induced by Peripheral Impression on the Pudic Nerve.—The speaker made some interesting observations in regard to the recognition of a respiratory and cardiac reflex induced by peripheral impressions on the pudic nerve. He recalled a case in which an alarming spasm of the glottis took place at the moment when the sphincter ani was stretched preliminary to the removal of hemorrhoids. The patient was, of course, anæsthetized. At the time it was thought that the anæsthetist was at fault in not having placed the patient sufficiently under the influence of the anæsthetic. But it was learned later that, however deep was the anæthesia, this reflex, though modified in degree, was present. Besides being induced by the stretching of the sphincter ani, it could also be caused by painful impressions upon the external genitals, and even upon the perineum and lower gluteal region. Sir William Macewan believed that impulses from almost every sentient surface might modify respiration. The heart also participated in this reflex through the vagus, but the effect upon it was seldom the prominent feature. It was, in reality, generally very slight. All of these reflex phenomena, due to stimulation of the pudic nerve, might be prevented or greatly lessened by local anæsthesia induced a little previous to the administration of the general anæsthetic.

The Choice of Suitable Material for Ligatures and Sutures.—The orator then devoted considerable time to the consideration of material for ligatures and sutures, and the requirements of the living tissue relatively to them. Aside from being physically fitted to perform its function, such material needed to be rendered aseptic; and further to comply with a physiological test. It must remain in the tissues until its object had been accomplished. After that had been attained, it should be quickly removable by absorption. It was well known that sterilized silk was practically non-absorbable. It was very resistant to the action of the tissues, during long periods. Silk-worm gut and hair were proof against absorption, and had been found at the end of five and even seven years after their introduction, quite intact, with their surface still smooth. Deer and kangaroo tendons, although they were absorbable, were resistant to the action of the tissues—often for months. It was well known that it was difficult to promote absorption of a sloughed tendon exposed in a wound. Long after the surrounding soft tissues were ready to unite, the presence of dead tendon would prevent their doing so. The orator believed that catgut was one of the best substances generally available for sutures and ligatures, but good material must be chosen. One of the best media for the preparation of catgut was obtained by adding an aqueous solution of chromic acid to glycerin. For ligatures and sutures raw catgut ought to be selected. Those pieces were best chosen which presented the best physical properties and showed care in their manufacture. It was clear that any further preparation would not remedy the original defects. Consequently, the most perfect specimens were the only ones that should be used. Poor specimens might be known by their want of strength or their roughness. The resistance necessary would depend upon the use to which the catgut was to be put. On this account, it was prepared with various degrees of resisting power. Some hanks were designed for rapid absorption, and some were intended for resisting the action of the tissues for longer periods. A precaution that should be observed was in regard to hardening. The gut must not be so hardened that it would prevent the penetration of leucocytes—otherwise it would be too resistant, and thus might not be superior to silk or even wire. The compound of chromic acid and glycerin above mentioned was found to act upon the catgut by increasing its resistance to the action of living tissue. The action of this compound produced a soft and pliable catgut, and the degree of resistance of the gut could be varied according to the length of time it was kept in the solution. The longer it remained in the solution the greater its resistance became. After it was prepared in this way it was stored in a solution of carbolized glycerin. After a fortnight's stay in the storage solution, it was ready for use. It might be kept in the storage solution for a long period—for months or years, and it then became slightly more resistant to the tissues. It must be remembered that if the crystals of chromic acid were added directly to the glycerin an explosion or violent

ebullition would take place. To avoid this an aqueous saturated solution of chromic acid was first made, and this was added to the glycerin in definite proportions as follows: (*a*) Chromic acid 1 part to 5 parts of water. Dissolve thoroughy and use only the clear solution. (*b*) Take one part of a solution to 5 parts of glycerin. After preparation this compound was at once poured over the loose catgut, previously arranged in a suitable vessel, all air balls which adhered to the gut being carefully removed. The catgut remained in this solution from one to ninety-six hours, as desired. It was then removed, rinsed in sterile water, stretched, and wiped with a sterile towel. It was then wound on rods and preserved in a storage solution composed of 1 part of carbolic acid to 5 parts of glycerin. The gut after steeping for a fortnight in this storage solution was ready for use. If the catgut was not wanted for immediate use, but six months or a year later, the storage solution could be made weaker, 1 part of carbolic acid to 20 parts of glycerin. Just before the catgut was to be used for a stitch or ligature, it was removed from the storage solution and dipped into absolute alcohol. This removed the superfluous glycerin. It might be dipped into sterile water for this purpose, but such a process softened the gut, and this was not desirable. It was no longer necessary, the orator concluded, to disturb the patient by dressing in order to remove sutures which, after they had served their function, would be silently and perfectly removed by the activity of the living cells in the patients' body. A wound which, while being made, was painless and remained so throughout, healed without inflammation or the production of pus, and under the dressing applied at the time of the operation, was ideally perfect.

The Nucleus in Malignant Neoplasms.—Peter Paterson's attention was first drawn to this subject by noticing the peculiar appearances presented by many of the nuclei in a carcinoma of the kidney, in which, owing to the protoplasm of the tumor-cells having undergone a colloid change, the tissue was specially suited for observations on the nucleus. Sections show a number of nuclei throwing out processes like pseudopodia. In some cases these projections are the first stage in the formation of daughter-cells by budding, but in others they are the beginning of a migration of the nucleus from its cell. Such a process reaches the cell-wall, through which it forces its way, and gradually the whole uncleus follows, thus leaving the cell without a nucleus, if it only contained one originally, though a considerable number of the cells possess two, derived usually from the primary nucleus by budding or fission. This wandering body is then found either in an adjacent cell or among the supporting fibrous structure of the tumor, where it may produce daughter-nuclei and become the center of a new cell formation, or it may coalesce with another similar nucleus. Coalescence takes place either directly or by means of a long process. The newly formed nucleus is large and deeply staining. Sometimes several nuclei fuse. Coincident with these phenomena, other nuclei are proliferating by mitosis. Some of these, when about to divide, extrude a small part of their chromatin substance. This part may grow till it resembles a lymphocyte. This extracted part gradually becomes separated from the dividing nucleus. It would almost seem that the process is analogous to the formation of polar bodies and the union of sexual elements, but in the case of malignant tumors the resulting nuclei are only able to reproduce cells similar to those from which they originated. As to what is the exciting cause of this alteration in the character of the nuclei, the writer can offer no definite opinion, but it seems more of histological than of a bacterial nature.—*The Practitioner.*

OUR LONDON LETTER.

(From Our Special Correspondent.)

CANCER RESEARCH FUND; ANNUAL MEETING—THE LIVERPOOL FUND—DR. WOLFF'S CANCER STATISTICS—TREATMENT OF CANCER, TWO REMARKABLE CASES—OBITUARY NOTES.

LONDON, July 15, 1904.

YESTERDAY the Queen went to the East End to inaugurate the flower show of the East London Horticultural Society. The proceeds of the show are to be given to the London Hospital.

The Prince of Wales presided over the third meeting of the General Committee of the Cancer Research Fund at Marlborough House when he announced that the King had approved of the fund being known in future a the "Imperial Cancer Research Fund." This recognizes the determination of the committee to extend the work as far as possible, and has the further advantage of distinguishing it from other organizations which were contributing very valuable investigations but are more local in their scope and perhaps more limited in their resources.

The report presented showed that investigations have been conducted on an extensive scale, and that the disease has been proved to pervade all classes of vertebrates and present constant characteristic features in them all, but is only transmissible from one animal to another of the same species. The extent to which cancer pervades the animal kingdom excludes numerous circumstances which have been suggested as possible causes, such as geographical surroundings, geological formation, climate, food, and other things which have been more or less loosely indicated. No sign has been discovered by which its presence can be surely detected; the circumstance which first causes a suspicion being too often a consequence. The report gravely counsels the public and the profession not to delay surgical aid, no attitude being "more strongly to be deprecated than that of procrastination—waiting for definite evidence of the cancerous nature of a suspicious growth."

The treasurer's report showed a further encroachment on capital and the annual expenditure is increasing. From the outset the promoters realized that the capital ought to be at least £100,000 and this has not been attained. Up to the present only 328 individuals and ten city companies have subscribed. There seems to be an impression that a few wealthy men will find all the money required, but this is not the fact and small gifts will be most helpful. The treasurer suggests collections by (1) ladies interested on account of the ravages of the disease on their sex; (2) large business and manufacturing firms; (3) colliery owners, so many of whose employees become victims. It is also suggested that insurance companies have pecuniary interests in the research and that the municipal corporations might legally and justifiably assist.

The views stated in the report are also largely the same as those entertained by the Liverpool Cancer Research Fund, the director of which, Dr. Grunbaum, has recently issued a letter to the press urging the importance of seeking advice immediately anything wrong is noticed. He mentions that certain organs are more affected than others; in men, the gullet, stomach, and intestines; in women, the breast and womb, which account for two-thirds of all the cases of cancer. Of course, these organs are also subject to other diseases, some of them of little importance. Dr. Grünbaum says his committee feels that it cannot too strongly state how important it is that the disease should be recognized at the earliest possible moment, and this recognition can only be attained by the patient going to his or her doctor for examination at the very beginning of illness.

With regard to the influence of the environment, I may say the conclusion stated in the report is not supported by the statistics collected by Dr. Alfred Wolff, who published them last year in the *British Medical Journal*, and has added to them in the current number. In England, France, and Germany he finds indications that geographical conditions play no small part in determining the incidence of cancer. In England, he says the distribution has always been patchy. It is difficult to explain this, but he suggests that the small size of the kingdom, involving considerable similarity in the conditions of life and in the distribution of natural features, such as wood and water, may have some influence. A similar patchy distribution obtains in Holland. It is otherwise in France where the high cancer mortality is mostly comprised in the northern third of the country.

In Germany and in France, thickly wooded, well-watered regions show a heavy death rate from cancer, and these new statistics seem to confirm the view previously expressed by Dr. Wolff, that a combination of woods with much water, running or stagnant, constitutes an environment, in which cancer will be prevalent, although the

mode of life of the inhabitants must also exercise an influence. The cancer death rate along the shores of the Mediterranean is low, so that climate may possibly have some influence in preventing the disease, though it is just as likely that some other explanation may be the true one.

To the foregoing I will add a note from another point of view—treatment. In the July number of the *Journal of the Royal Army Medical Corps*, two cases of inoperable cancer are recorded by Colonel Ligertwood, C.B., M.D., and Dr. J. A. Shaw-MacKenzie. They were treated in the Royal Hospital, Chelsea, with much relief and even apparent arrest. The first was cancer of the tongue of seven months' duration in an old soldier of seventy-three. He was treated with subcutaneous injections of soap solution as first proposed by Dr. Webb of Melbourne. Marked cessation of pain and of all factors, followed with diminution of growth, etc. Unfortunately the patient had advanced cardiac disease, from which he died, though the cancer was still receding.

The second case was epithelioma of the neck in a soldier of seventy-three. There was a hard, fixed mass, ulcerating in places; over the sternomastoid, great pain and dysphagia. The head was tilted on one side. He was treated with sterilized subcutaneous injections of chian turpentine in olive oil—5-minim doses of a three-per-cent. solution. Some reaction occurred when the dose was increased. Ulceration decreased, the discharge became purulent with no factor, the head could be moved again, dysphagia ceased and the mass diminished in all directions. The patient was in the convalescent ward in a month and goes out continually.

You will remember that chian turpentine was extolled some twenty-five years ago by Professor Clay of Birmingham as a remedy for uterine cancer. He gave it by the mouth. I well remember that for years it was freely tried but it fell into disuse. If other cases should be as successful as this, Colonel Ligertwood and Dr. Shaw-MacKenzie will have done well to reintroduce it by a more active mode of administration.

The death of Mr. John Birkett, ex-president of the Royal College of Surgeons (1877), which occurred on the 6th inst., severs a link with the long past, for he was in his ninetieth year and had retired from practice for a long time. He was a Guy's student and became a Guy's surgeon and consulting surgeon in due course. He was elected F.R.C.S. in 1844 and took the Jacksonian Prize in 1848. He was Hunterian Professor at the college, an examiner in surgery at the sister college and the University of London. Other offices and honors fell to his lot in due course. For many years he also held the appointment of Government Inspector of Anatomy. Mr. Birkett was not converted to antiseptic methods, but he may be regarded as a pioneer of asepticism, as he was most careful in preparing for operations by the minutest details of perfect cleanliness. He was a skilful and successful operator. He contributed to Holmes' "System of Surgery" the article on this subject, on which, also, he wrote in "Guy's Hospital Reports," of which he was for a time editor.

From British East Africa comes news of the death of Dr. Harold Edward Mann, medical officer of the Protectorate, at the early age of thirty-nine. He qualified in 1887 at the two colleges and took the Public Health Diploma in 1892. He was a St. George's student and afterward served as an assistant registrar at that hospital. Subsequently he took office under the Asylums Board as one of the assistant medical officers, in which capacity he worked for about five years. After that he secured an appointment to East Africa.

Dr. Unsworth, whose death is reported from plague at Zagazig, was a British officer in the service of the Egyptian Government. He was a St. Thomas's student and took the double qualification in 1899, subsequently serving as house surgeon and clinical assistant at his hospital. He was afterward an assistant medical officer at the Paddington Infirmary. Eventually he went to Egypt as an inspector in the sanitary service, Cairo.

Dr. Wm. A. McKeown, surgeon to the Ulster Eye, Ear, and Throat Hospital, and lecturer on ophthalmology and otology, Belfast College, died on the 9th inst., aged sixty. He was M.D., M.Ch.R.U.I. 1869, taking first honors and the gold medal. Before settling in practice he also studied for a time in Paris and London. He was on the Senate of his university and president of the Ulster Medical Society. He wrote a treatise on "Unripe Cataract," which contains tables of 152 cases, and contributed many papers to the medical societies and journals—chiefly on subjects connected with his specialty.

Norman Bruce Elliot, M.D., F.R.C.S., M.R.C.P., Barrister-at-law, died on the 4th inst. He took his first diploma in 1872. His fellowship in 1877 at the College of Physicians and M.D. in 1901.

Alfred Smith, L.D.S., 1880, surgeon to the National Dental Hospital for the last twenty-two years, died on the 6th inst.

Dr. John M. F. Scatliff of Brighton, died on the 3d ult., aged fifty-three. He was surgeon to the Brighton Throat Hospital and formerly physician to St. Mary's Hospital in the same town. He also held other appointments.

OUR BERLIN LETTER.

(From Our Special Correspondent.)

PHYSICIANS' ACCOUNTS—THE 1902 HEALTH REPORT FOR PRUSSIA AND FOR BERLIN—DECREASE OF THE CYSTICERCUS—GOLDSPOHN'S OPERATION—ABSENCE OF SPERMATOZOA—A CASE OF RENAL DIPHTHERIA.

BERLIN, June 25, 1904.

In an earlier letter I wrote that efforts for bettering the economical status of physicians on salaries were in operation, and now I have to mention a subject which interests particularly Berlin physicians, namely, physicians' accounts. For a long time it has been the custom in Germany for a physician to send his bill on the first of January following the date of his services. While in the smaller towns, because of the ease of identification, this signifies only a loss of interest, in the larger cities, through this method large sums are lost, since many patients often cannot be found. There are very few patients so grateful but that after a time they forget their pain, and consider even the smallest account from a physician too much. Therefore the association of physicians of the suburb of Oranienburg has proposed the passage of the following regulations by all the Berlin associations. (1) Physicians' accounts must be sent not later than three months after conclusion of the treatment. (2) Notes and promises from private individuals should be in the form of sight drafts. (3) Night calls on unknown persons are to be paid for at the time.

As Berlin in these matters stands at the foot, so, according to the recently published health report for 1902, it stands among the foremost of all the cities in the empire in that it has the smallest death rate. In all Prussia, in 1902, the mortality was the lowest since 1875, probably as the result of a cool summer, and also as the result of the decrease in the number of births. In the almost universal decrease in the birth rate in the last quarter of a century, Berlin shows the greatest change. The birth rate here fell from 46 in 1876 to 25.53 in 1902. For this reason the greatest city in the land has also the smallest death rate. While in the province of Schlesin the death rate is 23.35 per 1,000 inhabitants, in Berlin it is only 15.90, and this in spite of the very high infant mortality. If one compares the death rates of the twenty-two Prussian cities of more than 100,000 inhabitants, Berlin is found to hold the seventh place, surely very creditable. As far as child mortality is concerned, 1902 was a very favorable year, for it showed a notable decrease in almost all the large cities. Berlin, in spite of its great child mortality, was surpassed only by Dantsig, Stettin, Breslau, Magdeburg, and Aachen.

An interesting report is that of the society for the relief of accident cases for the year 1903, seven hundred and seventy-six persons applied to the bureau for instruction and information for the preparation of complaints. The chief part of the work is in the brush factory which now supports itself, its sales, amounting to 48,700 marks, having more than doubled recently. Therefore it is to be expected that this philanthropic association will soon be able to enter the much larger field of furnishing employment for those who are still more incapacitated than are those able to work in the brush factories.

It is hardly possible to depict the results of social philanthropy more clearly than did Hirschberg in the Medical Association in his address on the decrease of diseases caused by the cysticercus. An instance of the decrease and practical disappearance of a disease in the course of the last hundred years is seen in the leprosy of Europe. But the speaker had himself noticed in the case of the cysticercus that a disease may disappear even in the course of a generation. The cysticercus cellulosus was very common in Berlin in the middle of the last century. According to the observations of Graef, from 1853 to 1866, among 80,000 cases of eye disease there were 90 of cysticercus; from 1869 to 1885, among 60,000 cases, 70; from 1886 to 1894, among 73,000 cases, the speaker saw cysticercus of the eye only three times, and 2 of these 3 patients came from abroad. Between 1895 and 1902, among 65,000 cases, no cysticercus has appeared. The cause for this decrease is in the careful inspection of meat, and in the vigorous efforts made for more healthy animals. Tænia solium has, according to statistics, very greatly diminished in Germany—indeed it has hardly been noticed in Berlin in recent times.

Kossmann's paper on the Goldspohn operation, read in the Medical Association June 1, is of great practical value,

and the more so, because of the usual lack of success of operations for the relief of symptoms. Although formerly complicated cases of retroflection were not considered common, conditions have so far changed that retroflexion complicated with adhesions is now considered common, and the symptoms are recognized as depending on the adhesions. Goldspohn, choosing from the three methods, ventrofixation, vaginal or vesical fixation, and the Alexander-Adams' operation, has modified the last. He widens the inguinal canal on each side, so that with the finger behind the uterus, counter-pressure being made in the vagina if necessary, the adhesions can be loosened. An adequate shortening of the round ligaments hold the uterus, now freed from its adhesions, permanently in its normal place. Kossmann performed this operation frequently since 1899, with very good results. Duhrssen, the father of vaginal fixation, said that if one closed the peritoneal wound separately, as he had done for ten years, there could be no adhesions with the abdominal or inguinal wounds, and no disturbance would result during a subsequent labor. In the second place, by anterior colpocœliotomy one could observe the fundus of the uterus and also the posterior wall, even into Douglas's pouch, better than by the Goldspohn operation.

That the vaginal opening of the abdominal cavity in the hands of a skilful operator is certainly very easy, Duhrssen showed in three cases. (1) He showed dropsical appendix adherent to a right-sided pyosalpinx, which, by a complete vaginal castration, were removed together. (2) Through anterior colpocœliotomy, a tubal pregnancy in the fourth month, which had developed under the retrodisplaced uterus and the left adnexa, was removed, in spite of the fact that the sac burst. (3) In a woman five months pregnant the posterior vaginal wall was opened by a small incision, then the peritoneum of Douglas's pouch, and, with the aid of mirrors, the under side of a parovarian cyst, as large as a child's head, was engaged, punctured, emptied, the sac pulled out with forceps, and, after ligature of the pedicle, removed.

Henkel, before the Obstetrical and Gynecological Society on May 27, in his address on conservative surgery of myomata, advocated in general the abdominal route, because of the better view obtained by the operator. Of the women who had been operated upon there came for examination forty who had had myomata enucleated, and fifty who had had supravaginal hysterectomy. The latter operation prevented in great degree (80 per cent.) the appearance of prolapse. Among those who had undergone myoma enucleation, there were but five without symptoms. Lest the poorly nourished myoma capsule should cause difficulty, the speaker recommended its removal, and great care in bringing the well-nourished surfaces of uterine substance in apposition. The much-feared sarcomatous degeneration of myomata had been seen but once in thirty operations in Ölshausen's clinic, of which the speaker is chief, in the year 1903. Carcinoma is independent of myoma, and their appearance together is easily understood because both appear most commonly in the same period of life—that is, between forty and fifty years.

In the section on genitourinary diseases, on June 6, in the General Medical Association, a paper on diagnosis and treatment of azoöspermia was read by Posner and J. Cohen. The speakers stated that it has been for a long time known that disease, by blocking the seminal passage, might result in injury and inflammation, especially in the cauda epididymis. To-day we know that gonorrhœa is the chief cause, and a very common one. When called upon to treat a case of supposed sterility in a woman, one should always bear in mind the possibility of absence of spermatozoa in the man, and must not be deceived by the histories, for out of thirty-five cases occurring within three years, three men under oath denied former attacks of gonorrhœa. Usually no knots are to be felt when a hydrocele is present, but after puncture of the sac they are very evident. For curing azoöspermia, according to Fürbringe, it is first to be determined whether the apparently normal testicle contains spermatozoa. In several cases Hahn found for the most part only non-motile threads, but Fürbringe showed that motion was first given the cells in going out from the prostate.

The question of making an anastomosis between the testicle and the vas deferens was first suggested by Badenheuer in 1886, and then taken up by a pupil of Durant, and by Rasmowsky. Four Americans, Martin, Carmet Levy, and Pelling, through establishing such anastomosis, have succeeded in causing full restoration. The speakers in similar cases have not succeeded in the operations undertaken. They indeed treated the whole question because they believed that a complicated but successful operation could perhaps be planned out from another point of view, and accomplished with better success. Perhaps one would attain better results if the operation was done very early.

Krause has recently reported the marvellous success of an operation for diphtheria of the kidney. On account of slight cystitis, catheterization of the ureters was performed; the urine from the left was normal, but from the right no urine was obtained. The opening of the right catheter was filled with a greasy mass which proved to be necrotic tissue, and contained no bacteria. Since the pulse was almost imperceptible, the temperature 41°C, and repeated chills had occurred, the right kidney was exposed. The organ was not enlarged, and except for a cloudy parenchyma showed nothing abnormal. The pelvis, however, was filled with a greasy mass, which seemed to be a combination of necrotic tissue and uric acid deposit. For fear of infecting the peritoneum, the kidney was kept outside. On the next day the patient still had a high fever. During the twelve hours before the operation only 305 c.c. of urine were passed; the following twenty-four hours the amount rose to 950 c.c., and then to 1300 c.c. On the eleventh day the patient was without fever. The kidney had slipped back into place, and granulation tissue had almost completely taken the place of the foul deposit in the pelvis. During the following weeks a small fistula developed. Ten weeks after the operation, the kidney functionated, although but slowly. The large amount of albumin at first found in the urine of the right kidney had in the course of the last month decreased to a mere trace. The etiology of the disease could not be understood. The insignificant cystitis certainly was not a sufficient cause.

THE OVEREDUCATED WOMAN AND THE RACE QUESTION.

To the Editor of the Medical Record:

Sir: The native-born American woman has been the subject of discussion *ad nauseam* indeed. It seems never, or almost never, to occur to the medical profession that the condition of the male population has anything to do with the past, present, or future of the race; all depends upon the overtaxed brain of our educated women.

Has medical science reached that point where one can hope to see figs grow on thistles? Is there a law in physics that proves that we can hope for perfect development from blighted, contaminated seed; or can we transfer all weakness and inherited taint to the male population, and the female have no share but to rise out of the mire a glorified intellectual being with brain power sufficient to control herself and help control the universe.

When statistics tell us that ninety out of every one hundred men are or have at some time been afflicted with gonorrhœa, the deduction one would naturally draw is: that only 10 per cent. of the male population are capable of reproducing a normal healthy being, and yet almost nothing is said of this phase of human development, but all blame placed to the overtaxed brain of intelligent women.

The cry is what can be done for the boys. Teach them that they can be as bright, energetic, and resourceful as their sisters; that they have as much brain power, if properly cultivated and guided, and can attain heights morally, mentally, and physically impossible for those whose vitality is exhausted by wrong living.

From what source, if not from the medical profession, shall this change come? Come it must, and I for one shall be glad to see the profession, rather than these overtaxed women, undertake the work.

Josephine Kingsley, M.D

San Antonio, Tex.

Progress of Medical Science.

The Boston Medical and Surgical Journal, July 28, 1904.

A Case of Malignant Endocarditis with Recovery.—Charles F. Withington reports the case of a man of twenty-six years who had had an attack of gonorrhœa the month before he entered the hospital for sudden and severe pain in the cardiac region, and dyspnœa. The temperature was 102-105; pulse, 160-170. A thrill, presystolic in time, was felt below the nipple; gallop rhythm. A short systolic was heard in the fourth space to the left of the sternum. There were limited areas of consolidation in both backs. There was marked phlebitis of the left leg throughout its whole extent. Blood was taken from the vein at the elbow and showed, in the culture, gonococci. Few cases of gonorrhœal ulcerative endocarditis have occurred, the writer believes, in which pathologists have been able to demonstrate this organism intra vitam in the blood current.

Implantations of Silver Filigree for Cure of Large Ventral Hernia.—H. B. Perry describes the operation which he advocates, as follows: Up to the point of closing the hernial opening, it is identical with the operation for autoplastic repair. Then the omentum should, if pos-

sible, be stitched to the margin of the hernial ring. The sac is cut away, except that sufficient is left to close over without much tension. This is done with a continuous silk suture. The fat is then excavated sufficiently wide to admit the silver wire pad and permit stitching its border to the muscles and fascia. This is done with a continuous wire suture of sufficient length to have its starting and finishing points together, thus reducing to the minimum the rough points left. This completed, the skin and fat is closed over all by interrupted silkworm-gut sutures. The silver pad should be of sufficient size to overlap the margins on the opening from one-half to one inch. This plan is permissible only in the classes of cases in which autoplastic repair is impossible with any assurance of success from any or all of the following reasons: The large size of the hernial opening; a long existing hernia; atrophy through pressure and fatty degeneration of the adjacent muscular and fibrous tissues; previous unsuccessful attempts at autoplastic repair; and in fatty abdominal walls. The writer suggests this operation as worthy of trial in cases in which tissues already existing in the patient cannot be utilized to cure the defect.

Journal of the American Medical Association, July 30, 1904.

A Comparison of Phototherapy, Radiotherapy, and High-frequency Therapy in Skin Diseases.—Charles Warrene Allen, basing conclusions on nearly 450 personal cases, beside the 250 mentioned as having been subjected to high-frequency currents, makes the following statement: (1) In the vast majority of cutaneous affections the Röntgen ray is of greater utility than either the actinic or high-frequency methods. (2) In lupus the Finsen method, though tedious and disagreeable, is efficacious. The combined ray and high-frequency spark may prove to be equally good. (3) The actinic method is less beneficial in cancer than the Röntgen ray. (4) The high-frequency method is exact, no more disagreeable than the actinic, and for small lesions of epithelioma, lupus erythematosus, and many skin diseases gives quicker and better results. (5) All three can be advantageously combined for the different stages and phases of a large class of affections.

False or Cicatricial Cheloid.—A. Ravogli says the name cheloid was given by Alibert to neoplasms made up of connective tissue in the form of patches, strips, or tuberosities having identity with cicatricial tissue. One kind of cheloid is developed spontaneously in the derma, with which the cheloids are intrinsically connected, while others take their seat on the cicatricial tissue. After they have attained certain proportions they may remain without change indefinitely, though in rare cases they may undergo involution and disappear. One of the important features in the structure of the cicatricial cheloid is the nearly total absence of elastic fibers, and the growth of the connective tissue is greatly increased by this loss of the elastic fibers. From observations made it clearly appears that the destruction or the degeneration of the elastic fibers is the predisposing factor for the production of the cheloid. As a determining cause many have thought of a peculiar infectious pathogenic cause. In the case reported, on account of the locality and of the extension of the cheloids, no surgical operation could find any indication. The patient was suffering much pain, and a salve was applied containing resorcin, salicylic acid, olive oil, and lanoline. For three weeks this afforded relief, but later this treatment had to be discontinued because of the irritation produced. The irritation subsided under boracic acid, 5 parts in 100 parts of starch powder. Later they were treated with *x*-rays, which were applied for a few minutes two or three times a week, with rather satisfactory results.

The Consideration of Late Hereditary Syphilis.—R. R. Campbell says that at meetings of the Chicago Dermatological Society the question often arose. "Can hereditary syphilis manifest itself for the first time some years after birth by the presence of such late lesions as occur in the acquired form, and with a total absence of triad symptoms?" If long periods of latency may occur in the acquired form of syphilis, why may they not occur in hereditary syphilis? The triad of syphilis are Hutchinson's teeth, interstitial keratitis, and a particular form of deafness. Hutchinson's teeth are late manifestations of syphilis and appear not before the fifth or sixth year. These teeth are present in only a minority of those who are the subjects of inherited syphilis. Interstitial keratitis occurs usually between the ages of six and fifteen years, but may occur as early as the second or third year of life. Labyrinthian or central deafness is most frequently met with about the age of puberty, or in adults, being unilateral in the beginning, but in a few weeks or months becoming bilateral. The patient complains of noises, dizziness, and sometimes even attacks of vertigo. It is not improved by antisyphilitic treatment. Other diagnostic points of significance are acute ulcerative destruction of the soft palate in young persons, atrophic chorio-retinal plaques in both eyes, gummata of the skin, etc. Cases of latent hereditary syphilis are not very numerous in the literature. Brief reports of cases from the writings of different authorities are made.

Medical News, July 30, 1904.

The Value of a Knowledge of Abnormal Mobility of the Iris as an Acid in Diagnosing Diseases of the Nervous System.—D. Kerfoot Shute declares that in order to appreciate the significance of abnormal mobility of the iris in diseases of the nervous system, it is essential to understand the anatomical basis for normal pupillary activity and the appearance of the normal pupil. In disease, the dilatation of contraction of the pupil can be either irritative or paralytic, or both. Paralytic mydriasis is produced by an inhibiting disease, either of the pupil-contracting center or of the fibers that pass along the third nerve to the sphincter iridis. It may also be due to disease of the centripetal pathway between the retina and the oculomotor nucleus. The pupil is moderately dilated. Spastic mydriasis is caused by an irritation of either the pupil-dilating center or the pupil-dilating fibers going to the dilator pupillæ muscle. There is moderate dilatation of the pupil. Paralytic myosis is due to an inhibiting lesion of the pupil-dilating center in the mesencephalon or spinal cord or of the pupil-dilating fibers. Spastic myosis is caused by an irritation of the pupil-contracting center or of the pupil-contracting fibers. The pupil is moderately contracted and reacts very slightly to reflex stimuli. The value of a knowledge of pupillary abnormalities is well shown in the case of paralytic myosis. The small pupil in this condition is usually associated with retraction of the ball of the eye into the orbit and narrowing of the palpebral fissure, and is most often seen in aneurysm of the thoracic aorta or other mediastinal tumor, in chronic inflammations of the cervical part of the cord, and in locomotor ataxia. Spastic mydriasis occurs in irritation of the sensory nerves of the intestines by worms or intestinal tumors, in the spinal irritation of people suffering with anæmia after severe illness, in acute mania and melancholia, in paralytic dementia when it is associated with paralytic myosis in the other eye, and in hunger. While mydriasis in spinal diseases indicates an irritative process, in cerebral lesions it points to an extensive inhibiting disease of the brain. Spastic or irritative myosis is symptomatic of early stages of inflammatory diseases of the brain and its meninges; it is present in the early stages of epileptic and hysterical attacks; and in the early stages of intracranial tumors involving the third nerve. Another anomaly of the pupil is hippus. It is a normal clonic rhythmical spasm of the sphincter iridis. Both abnormal hippus and nystagmus are very important symptoms in the diagnosis of insular sclerosis. Abnormal or exaggerated hippus occurs in mania and other psychical disturbances. Nuclear disease of the oculomotor nerve is a common cause of symmetrical mydriasis, and may be developed by many causes. A lesion of the visual path between the optic chiasma and the cortical center for vision will cause the symptom known as homonymously hemianopsia. In locomotor ataxia the pupil is commonly contracted, though it may be normal or even dilated. In paralytic dementia the most common condition of the pupil is marked contraction of the sphincter iridis. The writer concludes by speaking of the different phases of mobility of the iris in chloroform narcosis.

New York Medical Journal, July 30, 1904.

Report of a Case of Lentigo with Unilateral Distribution.—John Irving McKelway says that the condition of freckles is usually found in individuals of a light complexion and having light hair, and the exciting cause is generally exposure to the rays of the sun; hence the regions most commonly affected are the face, backs of the hands and forearms, and is generally bilateral. The case reported is of interest because of the unilateral distribution of the disease, its occurrence in a woman with dark complexion and dark hair and eyes, the length of time the condition had existed (nine years and a half at least) without any appreciable change in the intensity of the pigmentation, and the fact that she was not a patient who spent much time out of doors, and was therefore exposed but little to the sun. A photograph, taken after her death, shows the distribution of pigment on her left breast, chest and arm, and, to a less degree, that on her face and neck.

Some Notes on Rigg's Disease and Its Treatment.—George F. Souwers says that if the tooth is in the preabscess stage, denoted by pain, a feeling of elongation and a sensation as though it were swollen and being crowded by its fellows, these symptoms being due to the formation of gas in and about the root, the proper procedure is to bore a hole into the root canal, this affording an avenue of escape for the gas. Then a mere thread of

absorbent cotton, wet with carbolic acid, oil of cinnamon, or other good disinfectant, should be carried up into the canal by means of a fine wire and allowed to remain. Free drainage is aimed at. The remainder of the treatment should be confided to the dentist. When the services of a dentist are not to be had and the disease has developed the gums should be cleaned thoroughly with peroxide of hydrogen, taking care to reach the recesses in the mucous membrane posterior to the last molar tooth. When the pus present has had its quietus, wash the mouth out with water and then apply aromatic sulphuric acid, basing its strength on the degree of evil present. All recesses, corners, and fistulous passages are treated, between the gums and necks of the teeth. Following the acid treatment, sodium carbonate and borax must be freely applied and the mouth again cleaned with water. The sulphate of quinine is dusted along the seat of the disease and lightly packed between the teeth. One thorough treatment of this kind will often stamp out the trouble, though it may be necessary to repeat it. The quinine treatment should be continued daily by the patient till its tonic effect is shown by the normal state of the gums being maintained. As an aid in the relief of the congestion of the gums a 1-1000 solution of adrenalin acts nicely. Where the teeth are sensitive on their lateral aspects to temperature changes, relief may be obtained by adding a few drops of phosphoric acid to oxide of zinc, the mixture to be of pasty consistence, and applying to the painful area.

The Management of Rigid Os in Labor.—Stanley P. Warren, in an editorial article, states that non-dilatability of the uterine outlet in labor is one of the curiosities of obstetrics and that tardy dilatation, or torpor, of the os and true stenosis are obviously two quite different conditions. Of the two conditions, the first is that which is most common, manifesting itself as a perversion of function rather than an arrest of it; the second, while being very exceptional, is anatomical only. The treatment of tardy relaxation, or what seems in certain cases to be mere torpor of the os is either temporizing or active. For the strong energetic woman the general line of management should be depressant, and an emetic will often do surprising good. Very hot normal salt douches, repeated every two hours or oftener, are of service. He also gives hypodermically a full dose of morphine and $\frac{1}{150}$ gr. of atropine. Complete relaxation follows this often within two hours. Reports are increasing in number of the good effects of cocaine, and there seems to be no general absorption of the drug when applied to the os even in massive doses. For the lethargic, anæmic woman, "rigid os" is a synonym for uterine apathy and mental stimulus is commonly more indicated than bodily. All distracting, well-meant interference of friends should be checked. In these cases he uses hypodermics of strychnine, $\frac{1}{30}$ of a grain, every three or four hours, supplementing occasionally by a single dose of ten grains of quinine. An occasional hot douche is beneficial for its local stimulant effect. "Everything is all right" cannot be told her too often. So far as the mechanical dilators are concerned he prefers the hand; under full anæsthesia rigidity yields to manual pressure more slowly than with metallic dilators, but more effectively than under the elastic hydrostatic pressure of rubber bags. Finally, careful, tentative traction against the resistant tissues with the forceps should be attempted, though its usefulness is restricted to the last half of complete opening.

American Medicine, July 30, 1904.

Carcinomatous Transformation of Ulcer of the Stomach.—John Dudley Dunham declares that the accurate work accomplished by numerous clinicians in all parts of the world would seem to furnish ample evidence that cases of cancerous changes in ulcer of the stomach do occur. The accumulation of the rough reports from such cases will probably show that cancer develops on ulcer more frequently than has been supposed. The ulcer is found at or near the pylorus in more than 50 per cent. of the cases. The process of canceration upon ulcer shows only a slight tendency to spread and invade the pylorus. The dilation of the organ is therefore less frequent. When the disease is well established, vomiting of food occurs very soon after its ingestion, which fact probably explains the moderate degree of dilation when present. The base of ulceration is generally made upon one of the neighboring organs. It is usually smooth and hard, as in chronic ulcer. The canceration begins in the pavement epithelium of the glandular tubules. Mayo says that of one hundred and forty-five cases of cancer of the stomach which came to operation under him, 60 per cent. presented a history of ulcer. Years may have elapsed before the cancerous process began. In the majority of cases the indications of ulcer continue until malignant invasion. This change is accompanied by an aggravation of the pain which at times is almost intolerable. Vomiting is excited by food. Small quantities of blood may be found in the vomitus, but there is rarely profuse hæmatemesis. Fragments of growth may be found after lavage. An increase in the hydrochloric acid is usually noted until very near the fatal issue. In another class of cases, the ulcer symptoms continue until the end. Profuse hæmatemesis may occur and perforation is not uncommon. In still another class, the ulcer symptoms may have subsided for months or years, and a recurrence of digestive difficulties which seems to indicate a return of the ulcer, may in reality be due to the beginning of the malignant growth. When the presence of the ulcer is established, the physician should impress upon the patient or his friends the gravity of the case. The classic treatment consists of rest in bed with rectal alimentation, followed by milk diet for perhaps four weeks. If the symptoms become more marked under this treatment, the diagnosis of conceration of ulcer is fairly certain. The treatment may be along surgical lines with a reasonable hope of prolongation of life, and along medical lines merely in a palliative manner. In cases of intractable chronic ulcer, gastroenterostomy should be employed to prevent the possibility of cancer development. Surgical interference is successful only when resorted to early in cases of development of cancer upon ulcer.

The Lancet, July 23, 1904.

On the Education of Visual Centers.—W. Hamilton Hall says that perhaps it is not easy to obtain clear ideas on the process whereby the "visual centers" acquire the power of vision, using vision to mean accurate perception of minute detail in the simplest degree. This faculty of instant recognition is usually deemed to be rather in the nature of judgment or intellectual perception than a matter of sight pure and simple, and it seemed to him worth while to describe in some detail an instance in which it can hardly be denied that imperfection of this faculty lay in the "visual center" of one eye exclusively.

One Form of Suppurative Appendicitis.—Arthur C. Roper reports three cases: in the first case there was a cascating gland; in the second there was a small and quite recent abscess with no acute symptoms at all; in the third, there was a large abscess. An interesting point was whether the gland is primarily attacked, which is unlikely, or whether it is secondary to some infection, tuberculous or otherwise, of the appendix or cæcum. He lacks bacterial evidence as to the precise cause of the suppuration, but the pus and abscess wall were strongly suggestive of tubercle.

Postdiphtheritic Chronic Bulbar Paralysis.—Wilfred Harris reports the third case of this kind that he has met with. The patient's improvement under large doses of strychnine and galvanism after so long a period as seven years is of great importance when compared with the recovery of one of his two other cases six years after the onset of the palsy, under the nutritional stimulus of pregnancy. He concludes that the nature of the lesion must be a slight form of nuclear lesion, not necessarily progressive, and capable in certain instances of being recovered from. All three of his cases commenced with palatal palsy and nasal regurgitation, from three to six weeks after an attack of ulcerated sore-throat. Two of his cases recovered, one completely after six years and the other partially after seven years, and the other, the most severe of the three, after suffering four years, was slowly becoming worse, the palatal palsy having become complete and laryngeal palsy beginning, while the eyelids and lips remain completely closed.

British Medical Journal, July 16, 1904.

Ozæna (Atrophic Fetid Rhinitis) a Cause of Gastritis.—Adolph Bronner speaks of the peculiar pale, ashy, complexion as being one of the most characteristic symptoms of ozæna, apart from the offensive smell. A bad taste in the mouth in the morning with vomiting, and no appetite, are other common complaints. These symptoms are due to the passage of the offensive nasal discharge full of bacilli into the stomach, and their deleterious action on the mucous membrane and on the contents of the stomach. In case any of the accessory cavities of the nose are affected, they must be opened up and treated. The writer advocates the use of formalin as a spray or douche. In bad cases he also applies trichloracetic acid or the galvanocautery to the diseased mucous membrane.

Mitral Stenosis in Advanced Life.—John S. F. Weir notes two cases of this nature. The first patient was a woman of seventy-three. She complained of pain in the left side and dyspnœa. There was a slight apical thrill, and a well marked presystolic murmur in the mitral area was audible. Necropsy showed an advanced degree of stenosis of the mitral valve, of the "button-hole" type, and there was a row of pale vegetations on the edge of the orifice. The left auricle was much dilated. The second patient was a man of seventy-three. He suffered from cough and emaciation. There was general bronchitis, though no heart

murmur could be detected. Necropsy showed a moderate degree of stenosis of the mitral orifice, of the funnel type, and a row of old vegetations at one part of the edge of the opening. The lungs were tuberculous.

The Incubation Period of Pneumonia.—Eustace M. Callender believes that the difficulty in fixing the definite incubation period in any disease must always be due in great measure to the difficulty in ascertaining the actual source of infection and the time of exposure. He publishes a series of five cases which are striking and instructive. The first patient was a girl of thirteen, who showed symptoms of a severe nasopharyngitis on the evening of May 8. On May 11 her left antrum was full of mucopurulent secretion. There was marked prostration, and the temperature was 102°F. The patient's father was well on the evening of May 10. On May 11 he was too ill to work at 1 P.M. He had a typical basal pneumonia, and died on the eighth day of the disease, of toxæmia. The third patient had two conversations with the last patient on May 11. He became ill on May 14, but the disease ended favorably with a very definite crisis on May 21. The fourth patient was, on May 12 and 13, in the sick room of case 2. On May 14 she was too ill to work. Her illness lasted for a week. The fifth case went into the room of case 2, on May 17. On May 19 she was taken ill and died of acute pneumonia on May 22. The writer believes that these were all cases of pneumococcus infection. The earliest period of infection appears to have been that in the case 4, a period of only forty-five hours. The writer had a precisely similar illness to that of case 1, and the mucopus was loaded with pneumococci.

Paroxysmal Tachycardia.—James Barr states that great frequency of the heart's action is a very common accompaniment of many morbid conditions, but the paroxysmal character of this affection, occurring in otherwise healthy subjects, at once marks it out as a particular entity, due, perhaps, to deranged physiological conditions, rather than to any morbific influence. The case reported is that of a youth who was suffering from tachycardia, the result of a blow on his epigastrium. He had another attack after another blow in the same place. The third attack followed overstrain from carrying a heavy load upstairs. Still a fourth attack followed an attempt to run away from a policeman. The writer at first associated the tachycardia with direct injury to the epigastrium, but in the light of the last two attacks he believes that the cause was acute cardiac strain. The very basis of these attacks lies in a hyperdistension of the right side of the heart, a hyperdistension which would quickly terminate the life of the patient were not the musculature in a healthy condition. During these paroxysms there was comparatively little cardiac distress, no anginal-like seizure, and no real dyspnœa. The patient could move about, and from his appearance no one would imagine that his heart was contracting over 250 times in a minute. If the heart were beating at this rate with a relatively low blood pressure, the distress and dyspnœa would be great. The patient would be bathed in perspiration, and death would quickly terminate the scene, but, fortunately, the regulative mechanism of Nature maintains the blood pressure, and with it the coronary circulation, until the right side of the heart gets rid of the load oppressing it. The writer sums up the treatment as follows: Put the patient in bed, freely use such agents as amylnitrite, nitroglycerin, etc., to lessen peripheral resistance and equalize the amount of blood in the two sides of the heart. Encourage the patient to take long, deep breaths, so as to aspirate the blood from the right side of the heart into the lungs, and thus give a better supply to the left ventricle. Counter-irritation might call into play the reflex cardiac contraction of Abrams. If, with this treatment, the hyperdistended right ventricle does not properly contract, then the addition of digitalis or of digitalin and strychnine is required. A good brisk purgative clears the portal circulation. The diet should be as dry as possible, so as to avoid the addition of fluid to the over-repleted veins and right side of the heart.

French and Italian Journals.

Atrophy of Both Testicles after Contusion.—Groussin had a patient, aged twenty years, who had had two attacks of mumps, one when he was six years old, and one when he was fourteen. It was eighteen months after the second attack that, in a fall from a wagon, he bruised the right testicle, which atrophied after two and a half months in bed. When he was twenty-one years old, he fell while climbing a mountain. The left testicle was pressed against a hard object in his pocket, and in its turn atrophied after two months in bed, made necessary by the traumatic orchitis which was induced. Groussin, when called to see the patient, tried injections of orchitic fluid. These injections seemed at first to yield some result on the left side, but were continued in vain. Later it will be possible to judge of any improvement, although it now appears doubtful if any will take place.—*Le Bulletin Médical*, July 6, 1904.

The Argyle Symptom and Meningitis Syphilitica.—Mario Bertolotti has studied the relation of the Argyle-Robertson pupil to the lesions of syphilis. He concludes that syphilitic spinal paralysis, in the great majority of cases, begins with a meningitis. The Argyll-Robertson pupil may often be found in the progressive meningomyelitis of syphilis; this tends to support the theory of Babinsky that this symptom is pathognomonic of acquired or hereditary syphilis of the nerve centers. The Argyll symptom is a phenomenon resulting from chronic syphilitic meningitis; this meningitis is the first symptom of all forms of syphilis of the nerve centers. It is not purely a symptom of tabes dorsalis, but may be found as well in general paralysis, cerebrospinal syphilis, hemiplegia, pseudo-bulbar paralysis, and meningomyelitis of syphilitic origin.—*Rivista Critica di Clinica Medica*, June 11 and 23, 1904.

Ovarian Cystoma, Papillary Carcinoma Ruptured into the Peritoneal Cavity.—Gulielmo Levi records a case of ovarian cystoma that had ruptured into the peritoneal cavity, and had then degenerated into a papillary carcinoma and involved the intestine. The patient was a young woman, married, but never pregnant. Her health had always been good. The first symptoms were enlargement of the abdomen, accompanied by intestinal symptoms, for which she was treated unsuccessfully almost up to the time of the operation. She had pain in the abdomen, and abundant leucorrhœa. The abdomen was enlarged to the size of a seven-months' pregnancy, more to the left side. There was free ascitic fluid in the abdomen. No symptoms of rupture of the cyst had at any time been noted by the patient. At the operation it was found that both ovaries were the seat of adenocarcinoma. There was also a large mass in the back of the abdomen attached to the intestines that appeared to consist of material that had escaped from one of the ovarian cysts, and had then degenerated into carcinoma. The growth recurred six months after operation.—*Archivio di Ostetricia e Ginecologia*, May, 1904.

Incipient Adenocarcinoma in the Mucosa and Submucosa of the Vermiform Appendix, the Cause of Repeated Attacks of Appendicitis.—Filippo Neri has made the pathological examination in a case operated on for relapsing appendicitis, in which he found the appendix to be the seat of a beginning adenocarcinoma. The patient was a woman of twenty-nine years, with the history of a blow on the abdomen, followed by repeated attacks of pain and tenderness in the right side of the abdomen. The attacks occurred every few weeks. At the time of the operation there was tenderness at MacBurney's point. The appendix was long, bent in a U shape, and occluded at one point. The point of occlusion was the seat of a new formation of the connective tissue type, poor in vessels, and with cells rich in nuclei, round, long, or branching. Among these were atypical tubular formations. The cells had always a round, nucleus, with small amount of protoplasm. The author makes the diagnosis of primary adenocarcinoma without metastases. Only eleven cases of this type are recorded in literature, all in young persons, and all associated with chronic appendicitis. He thinks that these cases are not rare, but are not recognized.—*La Riforma Medica*, June 8, 1904.

A Case of Tic of the Head and of the Trunk, Existing Only During Sleep.—René Cruchet describes this unusual case. The patient, when admitted to the hospital, was six years of age. The affection for which he was taken to the hospital had begun at the age of two years, and had never ceased, save for two months, when the child suffered from croup. These movements of balance were performed rapidly and only during sleep. The movements continued for different periods, 10, 18, and 20 minutes. Between these times he would rest completely for a half or three-quarters of an hour. He made from fifteen to twenty movements, one after the other, with an interval of about a second between them. To balance himself, he placed his left hand behind his head, the trunk being half bent over the pillow. The respiration was rhythmical. The exercise made the child warm, for he was red when he finished. His eyes were closed. To make him stop, it was necessary to waken him, or touch him on the tips of his fingers, or prick him gently with a pin. Then he would moan and stop. When he finished the movements he would lie down in bed quietly till the next series. On waking he remembered nothing of what he had been doing. Lumbar puncture met with negative results. Antipyrin administered to the little patient seemed to improve the condition, but the disappearance of the tics is far from being obtained as yet. —*Gazette Hebdomadaire des Sciences Médicales de Bordeaux*, July 3, 1904.

Book Reviews.

International Clinics. A Quarterly of Illustrated Clinical Lectures and especially prepared original articles on Treatment, Medicine, Surgery, Neurology, Pediatrics, Obstetrics, Gynecology, Orthopedics, Pathology, Dermatology, Ophthalmology, Otology, Rhinology, Laryngology, Hygiene, and other topics of interest to Students and Practitioners. By leading members of the medical profession throughout the world. Edited by A. O. J. Kelly, A.M., M.D., Philadelphia, U. S. A. With the collaboration of many well-known physicians here and abroad. Volume I. Fourteenth Series, 1904. Philadelphia: J. B. Lippincott Company, 1904.

Many very practical articles grace this issue of the "Clinics." Widal writes, in association with Javal, on the chloride-reduction treatment of parenchymatous nephritis; Edes on "What Is the Cure for Neurasthenia." Intestinal anastomosis receives consideration at the pen of John G. Clark. In the various regular departments, writers of reputation have contributed articles of interest and value. Progress for 1903 has been written up by Edsall, Bloodgood, and Stevens in a painstaking manner, in which is included an interesting chapter on tumors, well illustrated. One cannot fail to find much of general medical interest in looking over the pages of this volume, and the distribution of subjects is well made.

Obstetric and Gynecologic Nursing. By Edward P. Davis, A.M., M.D., Professor of Obstetrics in the Jefferson Medical College, Philadelphia, and in the Philadelphia Polyclinic; Obstetrician to the Jefferson and Polyclinic Hospitals; Obstetrician and Gynecologist to the Philadelphia Hospital. Second edition, revised. Philadelphia, New York, London: W. B. Saunders & Company, 1904.

The field of obstetric nursing, as the author states in his introduction, is a wide one. It includes the nursing of the patient during pregnancy, parturition, and the puerperium, as well as the care of the child. The obstetric nurse must be prepared to meet the emergencies of these conditions—accident, disease, or operation. She must have a thorough knowledge of, and experience in, asepsis and antisepsis. To this end the author has worked in the preparation of this excellent book, and although the size of this volume is very convenient, there will be found between its covers all the essentials of obstetric and gynecological nursing. To this second edition new material has been added, while the original text has been thoroughly revised.

Progressive Medicine. A Quarterly Digest of Advances, Discoveries, and Improvements in the Medical and Surgical Sciences. Edited by Hobart Amory Hare, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College of Philadelphia; Physician to the Jefferson Medical College Hospital; One time Professor of Diseases of Children in the University of Pennsylvania; Member of the Association of American Physicians, etc. Assisted by H. R. M. Landis, M.D., Assistant Physician to the Medical Dispensary of the Jefferson Medical College Hospital; Member of the staff of the Henry Phipps Institute for the Study, Treatment, and Prevention of Tuberculosis. Volume II. June, 1904. Surgery of the Abdomen, including Hernia, Gynecology, Diseases of the Blood. Diathetic and Metabolic Diseases. Diseases of the Spleen, Thyroid Gland, and Lymphatic System. Ophthalmology. Philadelphia: Lea Brothers & Co., 1904.

The contributors who have aided in keeping this June number of Digest up to standard form are J. C. Clark, W. B. Coley, Edw. Jackson, and Alfred Stengel. The article on Gynecology, by the first-named, discusses the ever-interesting question of uterine cancer. The extract on Pruritus Vulvæ gives an excellent insight into the causes, with hints on treatment based upon the latter. Pernicious anæmia, leukæmia, and pathological conditions of the blood in general are well and fully considered by Stengel. Altogether the work is one of much value for reference, besides giving in collected and readable form the evidences of progress for the year.

Medical Diagnosis. Special Diagnosis of Internal Medicine; A Handbook for Physicians and Students. By Wilhelm v. Leube, Professor of Medicine and Physician in Chief to the Julius Hospital at Wurzburg. Authorized Translation from the Sixth German Edition, Edited with Annotations by Julius L. Salinger, M.D., Late Assistant Professor of Clinical Medicine in the Jefferson Medical College and Physician to the Philadelphia Hospital. With 5 Colored Plates and 74 Illustrations in the Text. New York and London: D. Appleton & Company, 1904.

With the wealth of books on medical diagnosis in the English language a question naturally arises as to the necessity for translating a work on this subject from a foreign language. There was a time in the history of medicine when America had to borrow a good deal from other countries, but that time seems now past; just as it is growing year by year less necessary for the American graduate in medicine to go abroad to complete his professional education. The advances made by the medical schools and the medical practitioners of America have been so rapid and so marked, and the science and art of medicine have been raised to so high a plane, that many now living are likely to realize—in fact, have already begun to realize—the prediction that in the not remote future physicians will come from Europe and elsewhere to America to round out their medical education, as American physicians have for so long in the past gone abroad. So, too, it is growing less and less the practice to translate foreign medical works into English, while the translation of English works into foreign languages is becoming constantly more common. It is not to be expected, however, that the tide will be in one direction only. It is more likely that there will be a mutual and continuous interchange, and especially between the representatives of medicine on the two great continents.

Of Leube's Diagnosis, now in its sixth edition, it need only be said that it takes front rank among the works of its class, covering in a most thorough manner the wide range of subjects comprised in the field of internal medicine, and having regard for established modern methods of clinical investigation. The translation is, in the main, acceptable, although marked in many places by awkwardness of expression and involvement of statement from an apparent effort to be literal rather than free. Numerous additions have been made by the American editor, adding to the completeness of the text. There is a copious index of 50 pages. The book is well printed, moderately illustrated, and neatly bound.

Manual of Materia Medica and Pharmacy. Specially Designed for the Use of Practitioners and Medical, Pharmaceutical, Dental, and Veterinary Students. By E. Stanton Muir, Ph.G., V.M.D., Instructor in Comparative Materia Medica and Pharmacy in the University of Pennsylvania. Third Edition. Revised and Enlarged. Philadelphia: F. A. Davis Company, 1904.

The author presents his text in three sections. In the first part a few pages are devoted to botanical definitions as well as to definitions of names of therapeutic actions. The second part is given up to the consideration of individual drugs. While the third part, under the heading of Pharmacy, treats of processes used in pharmaceutical work; also of the preparations, especially those which are compound. Incompatibility is also discussed here. The lengthy detail often found in textbooks is omitted and the text is concise and clear. Only those drugs and pharmaceutical preparations are considered which are in every-day use, and which are of recognized therapeutic value. The drugs are conveniently arranged in alphabetical order. The metric system is used primarily.

Beiträge zur Anatomie der Tubenschwangerschaft. Von Dr. Fritz Kermauner, Assistent an der Universitäts-Frauenklinik zu Heidelberg. Mit 44 Abbildungen. Berlin: S. Karger, 1904.

In this little manual, in which the author has carefully reviewed forty cases, he gives the results of painstaking study of the condition of tubal pregnancy. The text is made clear and attractive by illustrations—44 in number. The different types of cases here described, with their varied histories, must prove of value and interest to those interested in this subject.

Physical Training for Children by Japanese Methods. A Manual for Use in Schools and at Home. By H. Irving Hancock, Author of "Life at West Point," "Japanese Physical Training," "Physical Training for Women by Japanese Methods," etc. Illustrated from photographs by A. B. Phelan. New York and London: G. P. Putnam's Sons, 1904.

This little volume of Japanese physical exercise is as attractive as it is valuable. The author in his introduction calls attention to the remarkable endurance of the Japanese soldiers, which is due to the training by their marvelous system of "Jiu-Jitsu" exercises. The course given in this volume is intended to fill up a school year. The exercises can be mastered in less time, but the writer thinks it advantageous to spend considerable time in reviewing those already learned. He would advise spending from twenty minutes to half an hour daily on this work. No separate exercises have been given for boys or girls. Besides the chapters on special exercises, there is one devoted to the consideration of deep breathing, food, bathing, clothing, and the effects of alcohol and tobacco on the health. The book has 134 illustrations, taken from photographs, which add much to the clearness of the text. Aside from the intrinsic value of the exercises themselves, the book teems with sensible advice by the author intended for both teacher and pupil.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held May 5, 1904.

ANDREW H. SMITH, M.D., CHAIRMAN.

The Treatment of Diffuse Peritonitis.—Dr. JOSEPH A. BLAKE read this paper. He said that the diversity of opinion in regard to the treatment of diffuse peritonitis suggested room for improvement. Cases of peritonitis were classified according to the extent and progress of the peritoneal involvement into localized and diffuse. The cases of localized peritonitis were those in which the products of inflammation were limited by adhesions; by diffuse peritonitis he understood an established progressive inflammation without definite limitations. These cases could be subdivided into cases of spreading peritonitis in which parts of the peritoneum could be demonstrated as free from invasion, and general peritonitis in which no part, possibly excepting the lesser sac, were uninvolved.

As to the time of operating, he still favored an early operation, as the patient had a better chance with the source of infection and the major part of the exudate removed, and as the shock of a quick operation was less dangerous than delay.

The methods of treating the exudate varied. All methods of cleansing the peritoneal cavity were open to objection. He endeavored to minimize as much as possible exposure and traumatism to the intestines. He used a small incision and irrigated with a large amount of saline solution by means of an irrigating tube with a central inlet and lateral outlets which connected with a siphoning rubber tube. This permitted a very rapid change of water without increasing materially the intra-abdominal pressure. By the use of this device the abdomen could be washed out in about one-quarter the time it took with the simple tube and less water was left in the abdominal cavity. The excess he allowed to remain, as it was quickly absorbed and a certain amount escaped through the wound.

In the matter of drainage, he had found it better to drain just through the wound, the drain only entering the peritoneal cavity for half an inch in those cases in which drainage of the peritoneal fossæ was thought unnecessary. The cigarette drain was used and removed in from thirty-six to forty-eight hours. This method had given a lessened mortality, a shorter convalescence, more rapid subsidence of temperature, shorter wound healing, greater freedom from meteorism and absence of intestinal obstruction. He never advised non-drainage in abscess cases.

The after-treatment consisted in complete rest for the alimentary canal. The stomach was washed out and no food given until the tendency to nausea was past. Nutrient enemata alternated with saline enemata were administered if nausea persisted.

During the last year Dr. Blake had operated upon 19 cases of diffuse peritonitis; 5 of these were generalized and 14 were spreading peritonitis. Of the cases of general peritonitis one was caused by appendicitis and died; two by perforation of gastric ulcers, with one death; one by rupture of the jejunum, which recovered; and one by what was apparently an acute pancreatitis, which recovered. Of the 14 cases of spreading peritonitis, 11 were caused by appendicitis and 3 by perforation of typhoid ulcers. There were 4 deaths among these, in 2 of which, so far as could be told by clinical evidence, the peritonitis had resolved; the other 2 deaths were caused by a persistence of the process. Grouping all the cases that he had operated upon last year with those previously operated upon, there were 51 cases of diffuse peritonitis, comprising 29 cases caused by appendicitis with a mortality of 28.5 per cent.; 5 by typhoid perforation with a mortality of 40 per cent.; 6 cases of perforating ulcers of the stomach or duodenum with a mortality of 50 per cent.; 1 by perforating ulcer of the ileum, which died; 1 by rupture of the jejunum, which recovered; 1 by acute pancreatitis, which recovered, and 8 cases by infection through the fallopian tubes, partly gonorrhœal and partly pneumococcus and streptococcus infections with a mortality of 62 per cent. The only cases of perforated ulcer of the stomach or duodenum that died were those in which the operation was deferred until twenty-four hours or more had elapsed after perforation. The comparative mortality in the whole series of 51 cases among the deeply and superficially drained cases was 14 deaths in 26 cases in which deep drainage was employed, while there were 5 deaths in 25 cases in which superficial drainage was used. In a number of the cases in which deep drainage was employed the very conditions which demanded drainage were the ultimate cause of death, but eliminating these there still remained a large balance in favor of no drainage or of superficial drainage only. Lavage of the peritoneal cavity was carried out in all but one of these cases, so that no comparative deductions could be drawn in regard to methods of cleansing the peritoneal cavity.

The main point in the treatment of diffuse peritonitis was that of early diagnosis. The latter symptoms of diffuse peritonitis—marked distention, regurgitation, flexed extremities, the facies, and depression from septic absorption—should never be awaited. He had never lost a case caused by perforation when the operation had been done in the first twelve hours, while most of the long standing cases had terminated fatally.

Dr. GEORGE E. BREWER said that a number of years ago McBurney operated successfully in general peritonitis following rupture of appendicular abscesses by making large incisions and using large amounts of gauze for drainage; prior to that time these cases were regarded as hopeless. Shortly after, surgeons went even further and practically eviscerated their patients, attempting to remove all the exudate. The mortality was enormous, and soon after, these methods gave way to methods approaching what was used to-day. He thought it was due to Dr. Robert T. Morris that the old barbarous methods were given up. Dr. Brewer's personal experience had led him to believe in simplicity of operation and minimum of drainage, and Dr. Blake's paper went far to fix in the mind and establish the fact that more modern methods, such as advocated, would give the best results. The early mortalities of 60 per cent. and 70 per cent. have dropped considerably during the past few years. He never completely closed cases of extending or spreading peritonitis but used small cigarette drains in the pelvis and, although it increased the danger of intestinal obstruction, he considered it to be a great advantage. He believed the methods detailed by Dr. Blake were far superior to those used formerly.

Dr. ELLSWORTH ELIOT believed that to-day all surgeons had agreed as to the advisability of (1) rapidity of operation, (2) thoroughness in the removal of the cause of the peritonitis, and (3) of removal of the products of the inflammation which were associated with the peritonitis. This was the best accomplished by lavage with the least possible disturbance of the intestines and subsequently, so far as possible, in drying the abdominal cavity. The tendency now was toward using less and less gauze for drainage. He had never yet depended upon the cigarette drain alone; if the incision was made in the median line this method of drainage could be employed, but he had been in the habit of inserting a rubber tube with the wick-gauze for the purpose really of keeping the opening apart. He appreciated the fact that many of the cases would recover without this precaution. In nine-tenths of the cases of localized abscess in the appendix, if the wound was closed, recovery would likely take place. In many cases the peritoneum was able to take care of itself and protect itself; therefore, why could not the same results be obtained after the surgeon had removed the cause of the peritonitis and cleaned the peritoneal cavity? So far as drainage

was concerned, he wished that surgeons had some means at hand by which they could tell the nature of the germs causing the difficulty; then they could be guided more accurately as to the necessity of using drainage.

Dr. Hermann J. Boldt took up the discussion from the gynecologists' standpoint. Gynecologists came in contact with two principal forms—the post-puerpural and the post-operative infectious. In the first, with a streptococci infection, the patients usually died within a very short time, and in the post-operative, if the infection was a severe one, the cases ran about the same course. He agreed with Dr. Blake in the statement that secondary openings of the abdomen after septic peritonitis usually resulted fatally. Reopening such cases was undesirable. The forms of peritonitis that gynecologists more frequently came in contact with was the gonorrhœal, the tuberculous, and the non-infectious form, the chemical toxic and peritonitis due to foreign bodies. In the gonorrhœal form the pus escaped through the fimbriated extremity of the tube and the peritonitis spread rapidly. As a matter of fact, he said the peritoneum did not offer a good medium for the gonococci to survive long and such infected patients often recovered. There was another class of cases which depended upon the pneumococcus, and he said whenever the pneumococcus was present one was sure to have a very virulent form of peritonitis to deal with, for these infected patients usually died within two or three days. Regarding the tuberculous form of peritonitis, treatment was very uncertain, and one relied upon abdominal section chiefly because it had offered a larger percentage of recoveries. But the statistics offered could not be relied upon. Tuberculous peritonitis might be in the dry form, or there might be a large tuberculous abscess in the peritoneal cavity, or, again, there might be a large number of tuberculous nodules scattered over the peritoneal surface, and the mortality in each of these varieties differed. The dry form offered the most serious cases to operate upon, and the most favorable form was that in which the tuberculous process was encapsulated. The treatment of the chemical toxic form depended largely upon the medications used and the amount of material escaped from the Fallopian tube into the peritoneal cavity. In the foreign body peritonitis he limited this to that caused by a twisted pedicle of an ovarian tumor or an ovarian cystoma; in these cases there was a spreading peritonitis following a localized one and, as a rule, the prognosis was good. So far as drainage was concerned, he preferred to drain through the cul-de-sac of Douglas and not with a small but a very large drain. Elevation of the end of the bed he considered a very important factor in obtaining good drainage.

Dr. Robert T. Morris said that no matter how suspicious the bacteria were, no matter whether proliferating or subsiding in their virulence, it seemed to him that there were two chief principles that should be considered, and these two apparently were in conflict: (1) We were to remove mechanically the fluid which was carrying the toxins and bacteria; (2) we were to conserve the natural resistance of the patient; the patient had a natural self-resistance and he acquired a new cell resistance in overcoming the bacteria that still remained active. If by the too careful removal of the fluid containing the bacteria and toxins we shock the sympathetic ganglia we interfere with the natural cell resistance of the patient and prevent the following out of the new cell resistance. Therefore, a very nice judgment was required in the treatment in knowing just to what extent we can mechanically remove the bacteria and toxins and to what extent we could depend upon the patient's natural resistance and his acquired resistance. In former years it was thought best to use large incisions and extensive drainage apparatus, and, although the septic fluid was gotten out, the patient was prevented from using his most valuable means for recovery and the statistics then were not very good. It seemed to him that cases did far better when no gauze was used because the gauze interfered with the natural resistance of the patient.

Regarding extensive flushing, he had employed the Chamberlin tubes, but to-day he never used them. He depended upon the lymph channels rather than upon mechanical means for the removal of the toxins and bacteria. The question of drainage he considered to be one of great value. If one washed out too thoroughly the toxins and fluid containing the bacteria, one may shock the patient too much, and, therefore, he had been inclined to wash less and less, and advocated getting in and out quickly and leaving the parts as much alone as was possible. He once advocated the closing of the abdomen in all cases of peritonitis, even when the bacteria were proliferating actively, after he had removed the chief amount of fluid containing the bacteria and toxins. In this matter one seemed to be between Scylla and Charybdis. This plan he had followed during the past two years when there was not much hemorrhage to furnish culture media. To-day it was a question whether this procedure was a wise one and for two reasons: (1) These patients recover quite as well as when the abdomen is left open and drained, perhaps better; but one was almost certain to have abscesses form in the fatty layer of the abdomen which did not heal kindly, and the patients might have a high temperature for some time and suffer more or less from the toxic impression upon their cells. So to-day he was not sure of this method of complete closure and he now placed in a small drain. (2) If he dried the peritoneal cavity he removed or injured the endothelium, which was wiped off very easily. If the endothelium was deranged but ever so little, the mouths of the lymph channels would be closed and so interfere with the rapid taking up of the septic fluid material. Attempting to dry the peritoneal cavity he believed to be wrong for this reason.

Dr. John A. Wyeth was in accord with what was said by the reader of the paper in the advocacy of the smallest possible incision with a minimum amount of trauma in the operative work. The infecting focus should be removed whether large or small. If it was small and possibly necrotic and not disseminated, he said the focus should be cleaned out and general irrigation omitted. But if there was a general distribution of this necrotic septic material then thorough irrigation with saline solution under high pressure should be employed. He did not believe in attempting to dry the peritoneal cavity on account of the trauma that necessarily must be produced. With regard to the question of drains he differed with some, because he believed that the cases he had lost were due to his failure to secure satisfactory drainage, and he now made it a rule to drain by a cigarette or gauze drain from the focus of infection. He believed it was very important in general diffuse peritonitis to prevent the dangers of absorption, and he advocated keeping the patient in Fowler's position. The pelvic portion of the peritoneum should be drained, especially the cul-de-sac of Douglas, as advocated by Dr. Boldt.

Dr. John B. Walker said that the line of treatment depended upon the nature of the organism, and he believed in eliminating any serum or culture media which may be present and in which the organisms may grow.

Dr. Frederick H. Wiggin said that gauze in the abdominal cavity favored the formation of adhesions. In cases of peritonitis he used the small drain. It was almost impossible to prevent infection of the abdominal wound, and, therefore, he left a small drain in until the wound became clean and healthy granulations sprang up. In certain cases, such as peritonitis following a gangrenous appendicitis, with the abdomen much distended, he opened the abdomen and let out the excess of fluid more for the purpose of relieving the pressure upon the heart and lungs. He deprecated too much interference in the peritoneal cavity. The most severe forms of peritonitis he had met with were those which accompanied an appendicitis with an unruptured appendix.

Dr. William Bryan, West New Brighton, S. I., said he did not use the Chamberlin tube at all now, but did use a small cigarette drain. His results were now better than formerly, probably because of smaller incisions, shorter operations, and less traumatism. He agreed with Dr. Morris in the wonderful properties the peritoneum showed in being able to care for itself and getting rid of any infectious material.

Dr. Franz J. Torec reported eight cases of general peritonitis which followed appendicitis, with recoveries in all, and with different methods of treatment than those referred to by the reader of the paper. His incision was made very long, and was always the median one. He always selected the median incision whenever he found rigidity of muscles on both sides of the abdomen and this appeared in all of his eight cases. He believed in thorough flushing of the abdominal cavity, not using a tube, but pouring pitcherful after pitcherful into the cavity and moving it about with a rubber covered hand. In all these eight cases the wounds were closed completely, not even using a cigarette drain. In three of the cases he obtained primary union and three developed suppuration along the stitch canals; one developed an intramural abscess along the line of incision and one developed an intraperitoneal abscess. All were emergency cases. Early operation he considered to be of prime importance. Patients operated upon later than forty-eight hours gave very poor prognoses.

Dr. A. A. Berg made reference to some studies made at the Mt. Sinai Hospital. Five years ago a very large number of desperate cases of diffuse purulent peritonitis were met with in the emergency service, and it was concluded that the existence of a purulent exudate in the peritoneal cavity did not always mean a purulent peritonitis. Many of the cases that came to operation showed a diffuse purulent exudate of most fetid character, and in both spread and culture showed streptococci and staphylococci and the bacterium coli. Although not drained or washed out, some of these cases did remarkably well. What a purulent peritonitis was he had not yet decided. He believed the peritoneum could absorb very rapidly if normal, but if it was found to be less shiny or glistening then it had less absorptive power. Every case of modified peritoneum should be provided with drainage; if not drained, then he said one must expect abscesses, for these modified areas would be the starting points for fresh infections, which would spread over the peritoneal cavity. He guarded against the complete closure of the abdominal wound in these cases; this was only permissible when one was certain that the peritoneum was intact or unmodified.

Dr. A. V. Moschcowitz said there were two methods of treating these cases, one the dry method and the other as reported by Dr. Blake. With irrigation his results had been bad, but in justification of this method he said he had only treated the very bad cases.

Dr. Blake, in closing the discussion, said that his reason for stopping drainage was given in a former paper, and he did so because he could not drain the *entire* abdominal cavity. He also said that anyone must concede that washing or cleansing was necessary in the cases in which there was foreign material, either extravasated gastric or intestinal contents or fibrinous products of inflammation. In the cases in which there was only a seropurulent or purulent exudate, washing was not so important.

The Latest Cure for Appendicitis, as announced by cable from Berlin, is for the patient to walk on all fours for twenty minutes, four times a day. The theory on which this treatment is based is that certain muscles around the vermiform appendix are brought into play and strengthened by this quadrupedal cure, which are unused when a biped walks erect. Others are relaxed, and the localized inflammation has opportunity to subside.—*Medical Times.*

NEW YORK ACADEMY OF MEDICINE.

SECTION ON GYNECOLOGY.

Stated Meeting, Held June 2, 1904.

Dr. A. Palmer Dudley, Chairman.

Ovarian Cyst with Twisted Pedicle Complicating Pregnancy.—Dr. L. J. Ladinski presented this specimen which he had removed from a patient, twenty-three years old, who had been married five months and who menstruated regularly until three months prior to admission to Beth Israel Hospital, April 8, 1904. For some weeks she had noticed marked enlargement of abdomen with some pain, especially on the left side. Four days prior to admission she was seized with sudden lancinating pain on the left side of the abdomen which compelled her to take to bed. These paroxysms of pain increased in severity, requiring morphine for relief for four days; then Dr. Ladinski saw her in consultation. The patient was then bordering on collapse, was somewhat cyanotic, pulse 140, rapid and labored respiration, very restless, with a normal temperature. The abdomen was distended with a tense, globular, fluctuating tumor, tender and sensitive to touch. The percussion note was flat in the median line and dull in the flanks, the latter disappearing on change of position. Evidences of fluid were obtained. Vaginal examination showed the uterus to be enlarged to about the size of one in the third month of pregnancy, and there was fluctuation in the anterior wall. The uterus was wedged down in the pelvis, and the vaginal vaults were bulging and tense from the pressure of the intra-abdominal fluid. Operation was advised. On opening the abdomen a large quantity of bloody, ascitic fluid escaped. The cyst wall was congested, black in color, especially toward the lower part. The pedicle was found to be twisted one and a half times to the left and sloping from the right side. Recovery was uneventful and pregnancy was not interrupted. He said that Platon and Ironé (*Marseille Médicale*, May 15, 1902) reported a case similar to his. Torsion of the pedicle in an ovarian cyst was a quite frequent accident during pregnancy, particularly when the uterus began to rise out of the pelvis into the abdominal cavity. These authors quoted Remig's statistics of 45 cases in which operation was performed, with the following results: During pregnancy, 18 patients, 10 recovered and 8 died; during labor, 15, 7 recovered and 8 died; during the puerperium 12, 4 recovered and 8 died. D'Sirne (*Archiv für Gynäkologie*, No. 24, page 154) collected 109 cases of ovarian tumor complicating pregnancy, in 10 of which, *i.e.* about 9 per cent., there was a twisted pedicle. Petritchek (*Centralblatt für Gynäkologie*, No. 26, 1900) reported a series of 30 cases collected and 2 of his own of ovarian cysts complicating pregnancy; in 26 cases twists of the pedicle had occurred. The diagnosis of torsion of the pedicle was made in only 3 cases prior to operation. Dr. Ladinski could find no more cases in the available literature.

Pseudohermaphrodism.—Dr. L. J. Ladinski presented this interesting specimen which was removed from a patient thirty-nine years old. During her eighteenth and nineteenth years she had had a slight menstrual discharge at irregular intervals, but had never menstruated since. She had had epistaxis off and on for many years, but was never ill before. The present history showed a right congenital hernia which had increased in size recently and caused her pain. Vaginal and rectal examination showed no cervix, uterus, or adnexa; the vagina was of normal depth, but ended in a blind pouch and was drawn toward the right side. The labial hernia of the right side descended to the perineum and presented, in addition to a coil of intestine, a smooth and hard ovoid mass the size of a hen's egg. The entire hernial contents could be reduced. Operation was performed at the Beth Israel Hospital October 20, 1903. Incision was made over the

right inguinal canal and extended down the labium. The hernial sac was freed from adhesions, drawn out, and incised. The sac contained coils of intestine. The outer half of the sac presented no unusual features, but the inner portion consisted of a broad, thick fold of tissue resembling the broad ligament, to which a hard, smooth, irregular mass was attached. The tip of the appendix was attached to the base of the sac. This was freed and the appendix removed, and the outer portion of the sac and as much of the inner portion as could be separated were then ligated and reduced. The mass which constituted the greater portion of the inner part of the sac was ligated in sections and removed. What appeared to be the round ligaments and the ovarian artery traversed the mass. The canal was then closed in the usual manner.

Dr. Ladinski had presented the specimen to Dr. F. M. Jeffries for examination and the report was made that sections of the mass revealed portions of uterine tissue, tissues from the testicles and probably also the prostate, although the last was somewhat in doubt. There were, corpora amylacea of a character resembling those found in the prostate. Both uterine and testicular structures were somewhat in an embyronic state. He concluded that he was dealing with a case of hermaphroditism.

Dr. A. Palmer Dudley said that, a few years ago, a true case of hermaphroditism appeared in the Harlem Hospital. The individual was sixteen years old and came into the hospital on account of pain in the right iliac region below the seat of the appendix. He then discovered that the person was an hermaphrodite and as true a one as he had ever seen. There was one testicle, one labium majus, one nympha, and a clitoris as large as the middle finger. There was no urethra. There was a gutter or narrow structure between the two crura perfectly formed. There was a small vagina and a hymen and by rectal and vagina examination there were discovered an immature uterus and a small ovary. The individual voided urine through the perineum. The person had all the psychological characteristics of both woman and man.

Specimens of Fibromata.—Dr. L. J. Ladinski presented the following three specimens of fibromata, not because they were of unusual interest, but simply as types of cases which had happened to come under his care recently. During the past few months he had had occasion to do eight hysterectomies for fibromyomata by the abdominal route, and all of the patients made uninterrupted and rapid recoveries. In none of the cases was it justifiable or advisable to do a myomectomy, because of the age of the patient, of the character and size of the tumor, or of the extent of involvement of the uterine wall. When possible one or both adnexa were retained. In most of the cases the indications for operation were pressure symptoms, and in some uterine hemorrhage. All these patients were operated on by him at Beth Israel Hospital with the exception of one who was operated on in private.

Case I.—C. P., aged thirty-eight years, married eighteen years, four children, youngest eleven years, had profuse and irregular menorrhagia for past three years, especially during the past few months, with pain in the abdomen, frequent and painful urination, and constipation. The abdominal tumor extended to above the umbilicus. Abdominal hysterectomy was performed April 5, 1904. In this case the tumor extended down to and involved the cervix, necessitating complete extirpation. The patient had a rather slow but good convalescence.

Case II.—N. S., aged thirty-three, married nine years, three children, the last child four years ago; during the past twelve months she had profuse menorrhagia and constant severe pain in the pelvis. She was operated on at Beth Israel Hospital, March 17, 1904. The tumor filled the entire pelvis and was intimately adherent to the intestines and omentum and the walls of the pelvis, and especially to the bladder and rectum. The left ovary was found to be cystic. Abdominal hysterectomy and supravaginal amputation of the cervix were performed. The right adnexa were retained. The patient was discharged from hospital April 9, 1904.

Case III.—B. S., aged twenty-nine, married ten years, two children, had profuse menorrhagia for six months and pain in the abdomen and pelvis. The patient was in a very debilitated condition. The tumor extended to the umbilicus. Abdominal hysterectomy and supravaginal amputation were peformed. Both adnexa were cystic and were removed. The patient was discharged March 26, 1904.

Uterine Fibromyomata.—Dr. A. Palmer Dudley presented these specimens, which he had removed from a housewife who had been married thirty years and widowed twenty-six years. Her last pregnancy was twenty-seven years ago. She had been sick for seven years and had had menorrhagia since last November. There were no vaginal discharges and no vesical symptoms. Locomotion was good. She had been in fair health until recently. Her bowels were regular and the appetite was good, but she was flowing at the same time when seen. Her present symptoms were flooding and pain in the left side. Physical examination showed a large growth in the right side and a smaller one in the left. Curettage was first performed without drainage. Cœliotomy was next done, the adhesions were broken up, the appendix was removed, and a large fibroid was removed from the right and a smaller one from the left side of the uterus; gauze drainage was introduced from the tumor cavities through the uterus and also gauze drainage from the abdomen through the cul-de-sac. The uterus was suspended. The usual after-treatment was given and the patient made a good and rapid recovery. She drained freely for over a week, was up in two weeks, and left the house at the end of three weeks.

Rectal Constipation in Women.—Dr. Grace Peckham Murray read this paper. (See page 201.)

Dr. Samuel G. Gant spoke of another causative factor not mentioned in the paper and that was the wearing of pessaries, which produced a mechanical impediment to the movement of the bowels. Very often he said it was difficult to determine whether the trouble was in the rectal or in the sigmoid region. As a result of pelvic inflammation and tubal inflammation the sigmoid frequently became involved in a mass of adhesions and bound down. The sigmoid might be much elongated and obstruction be caused by the formation of a loop. Again there might be an over-development of O'Beirne's sphincter, *i.e.* an increase in the number of circular fibers. All this was productive of constipation. As to the fæces going back into the sigmoid when the bowels were not emptied, he believed that occurred once in a while, but not as a regular thing. It was O'Beirne who offered the theory that when a patient had the desire to go to stool and did not then the fæces would go back into the sigmoid; that might happen occasionally. In preparing patients for operations it had frequently been noted that after clearing out the bowels thoroughly small particles of fæces would come down into the rectum, and by stripping the sigmoid then the bowels could be more thoroughly emptied. The treatment of such a condition was a very difficult matter. As a result of pressure of the uterus against the rectum, so common in women, making it even difficult to use the proctoscope, the congestion of the hemorrhoidal vessels that was produced increased the constipation. Another common cause of constipation was a narrow anus, caused either by pressure from without or by spasmodic contraction. His treatment of all these cases of constipation was carried out on these lines: The women should be properly educated; the sphincter, in many instances, should be divulged, but this was seldom necessary. He believed the rectal valve produced obstruction and constipation; as a result of a catarrhal condition, the valve became thickened and produced obstruction so as to prevent the free escape of the

fæces. Here he thought it was proper to divide the valve doing a valvotomy, according to the plan of Martin. In women sometimes one met with a membranous colitis and if, during such an attack, a proctoscope were introduced, there would be found a large flow of mucus from above the valve. Valvotomy should not be done in every case of constipation; he did not mean this. The principal thing to do in these cases was to educate the patient properly, and massage was a very valuable adjunct, especially by means of vibration.

Dr. James P. Tuttle said that occasionally he ran across cases in which the valve seemed to be at fault, and he then felt perfectly justified in clipping it off. Anterior rectocele had been spoken of; there was no doubt but that there was a lodgment of the fæces in such a condition, but there was also a posterior rectocele in which the fæces lodged, and which was fully as important. Masses of fæces could be found in the posterior cul-de-sac as well as in front, and one gave as much trouble to cure as the other. When there was a deficient perineal body, that must be attended to, and a new one should be formed in order to do away with the rectocele. He then referred to the lack of contractile power of the rectal muscles in individuals who had been victims of periproctitis; there was not actually a stricture produced but the rectal wall had lost its power of contraction. Nothing but abdominal force and washing out the rectum would relieve the condition. It was sometimes the result of peripelvic inflammations. Another condition often met with was what was termed "rectal hernia." In this there was an elongation of Douglas' cul-de-sac and the pressure forced the intestine down into the rectum; this condition was often diagnosed as a prolapse of the rectum; it presented one of the most difficult problems in the way of treatment. Another condition causing constipation, which was frequently overlooked, was an interstitial neuritis occurring around the margin of the anus in patients with fissures that had healed and left not a big cicatrix but a small one. Here the nerve had become involved in the plastic process and there had resulted a true neuritis. This interstitial neuritis was the cause of constant aching pain, which increased every time the bowels moved and on long sitting; as a result the patients dreaded going to the closet. Stretching the sphincter in these cases was absolutely useless. The only thing to do was to dissect out the entire deposit and then one would get rid of the constipation; the deposit should be dissected out and a plastic operation should be performed.

Dr. James J. Walsh said that during the past few years there had been a great change regarding the possibility of autointoxication occurring as the result of constipation. He did not regard the danger as great, for when one was constipated the water was more or less extracted from the contents of the bowel, and this lessened the tendency for bacteria to grow, making a poor culture media.

Dr. Gant said that he had had many cases of colitis occurring in patients with bad complexions; so soon as the colitis had been cured the complexions improved.

Dr. A. Palmer Dudley spoke of the constipations that were due to passive congestions about the uterus and adnexa resulting from the manner of dressing in women, which crowded the uterus and appendages down upon the bowel structures; then chronic constipation resulted, which brought about a condition of colitis as a result of the packing.

Dr. Murray said that her paper was addressed more to the general practitioner than to specialists. She said that the former frequently gave cathartics without understanding the conditions producing the constipation. This was shown in the cases of mechanical obstruction so frequently met with. She recognized a defect in the paper in not having given more prominence to the inflammatory conditions producing constipation; they were mentioned only incidentally. The mention of autointoxication brought to mind something she had thought of while writing her paper, viz., personal idiosyncrasy in regard to it. Many patients would go for a long time without any movement of the bowels and without any evidences of autointoxication. Regarding anterior and posterior rectocele, it was the anterior that she had observed most frequently in women, and this was the one treated of especially in her paper.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held May 23, 1904.

Dr. Wendell C. Phillips, Chairman.

The Passing of Neurasthenia.—Dr. Charles L. Dana read this paper. He said that the term neurasthenia by some was thought to be a reflex neurosis while others claimed that it was of central origin. For years Dr. Dana had met with many cases of melancholia, and in a series of one hundred cases more than one-half gave histories of what had previously been diagnosed as exhaustion, and he came to the conclusion that a large percentage of neurasthenics in the middle and later life were forms of melancholia. Simple melancholias he always considered to be curable. There was a tendency to recur, and it was usually easy to diagnose between the psychosis and the neurosis. More than one-half the cases of so-called neurasthenia could easily be regarded as cases of melancholia, or this plus some real non-psychical exhaustion. He said there was one general psychosis which took place in three forms, viz., (1) simple melancholia which was not always recurrent and which was oftentimes seen in adults; (2) melancholia or maniacal disease in which there were attacks of mania or melancholia, or both, which occurred early in life; (3) hypochondriacal melancholia. He stated that neurasthenia might be confounded with the melancholias of involution. He also referred to another group of cases, neurasthenic or hystero-neurasthenic, the form that occurred in adolescence. Hysteria had been recognized as a psychosis and belonged to the same group. There again was a group of insanities known as the exhaustion or toxic psychosis which was produced by and followed certain infectious diseases, such as typhoid fever and influenza. There was an important group of insanities which appeared before the period of adolescence and these were sometimes called the insanities of adolescence, the more modern name being dementia præcox. This was preceded for two or three years by pseudo-neurasthenic symptoms.

The so-called neurasthenia occurring before the age of twenty was apt to be a serious psychosis. Paranoia was a form of insanity, but here the symptoms do not develope in manifestly or evident psychosis. For some time these cases go on to fits of depression, to suspicions, they become hypochondriacal, and they pass as cases of neurasthenia or melancholia of adolescence, whereas they are really developing paranoia.

In summarizing his remarks Dr. Dana said that from one-half to two-thirds of the so-called cases of neurasthenia might be grouped under the headings already referred to, including the early stages of paresis. Still there were many cases that must yet be called by that name. In examining these cases of so-called neurasthenia one should make an attempt to classify them properly. It was stated that in the Boston and Massachusetts General Hospital they had not made a diagnosis of neurasthenia more than twice during the past twelve months and, therefore, Dr. Dana felt justified in calling the attention of the society to the fact that one must look further when meeting with such cases. Ten years from now this term will have been dropped or else applied to a very small group of cases.

Dr. Robert T. Morris said he was glad to hear what Dr. Dana had stated regarding the classification of these so-called cases of neurasthenia and to know that more than

one-half of them were really psychic in origin; this would greatly simplify matters. Surgeons saw a great many cases of neurasthenia which developed soon after surgical operations. Many of these were cases of psychosis precipitated by, for instance, a loose kidney, by peritoneal adhesions, eye strain, septic endometritis, and other causes which did not really cause but rather precipitated an attack. Hereafter he would consider these forms of so-called neurasthenia as really forms of psychosis precipitated by some peripheral irritation.

The Curette in the Treatment of Acne.—Dr. George Henry Fox read this paper, and said that he would like to impress upon the members of the society what it had taken him thirty years to learn, viz., the use of the curette was worth more than all the ointments and lotions that had ever been recommended from time immemorial and commonly used at the present day. He had used it for many years to the exclusion of remedies usually employed by others. By its use there were left a number of bleeding points, and patients, as a rule, were not impressed with it at the outset; but gradually the comedones were eradicated and marked improvement followed in the patient's complexion. The pain or discomfort lessened with the disappearance of the acne lesions. After using the curette he rubbed the face with some antiseptic lotion. The inflammatory condition quickly subsided without the use of soothing ointments. During the treatment the patient should massage the face, bathing first with cold water and then scrubbing it with a rough towel. Steam was rarely advisable. Cold water acted as a local tonic. He did not claim that the curette would cure all cases of acne; it would improve a toper's nose but it would not cure without changing the habits of the patient. The curette was the best method of local treatment, but the general treatment should not be neglected. The patient should be placed upon a rigid and restricted diet, and one should insist upon plenty of exercise in the open air. Every patient with acne was anxious to be cured, and he said that they all could be cured if attention was paid to the following three things to be employed, viz., diet, exercise, and the curette.

Dr. Wendell C. Phillips said that he had recently seen such remarkable results following the line of treatment advocated that he was much impressed with it.

Report of Rectal Operations Under Sterilized Water Anæsthesia.—Dr. Samuel Gant make this report and presented patients upon whom he had operated by this method of anæsthesia. He said he was led to use it because so many patients objected to anæsthetics or to anything that would keep them from business. He had experimented with local anæsthesia and finally got the solutions weaker and weaker, and then he observed that it did not make much difference how strong the solution was so long as it was introduced in a certain manner. He had operated upon minor cases, such as hemorrhoids, fistula, fissures, prolapses, etc., and with marked success, and without the bleeding that almost invariably followed the use of eucaine or cocaine which seemed to paralyze the blood-vessels and cause much oozing afterward. Within thirty seconds he could completely anæsthetize the parts to be operated upon. He had done more than 250 operations under sterile water anæsthesia. It could be used in other parts of the body. The injection was first made beneath the skin, and this was the only painful part of the procedure; this caused a sharp stinging pain lasting but a short time. The sterile water should be injected between the layers of the skin until a white line appeared showing the part to be completely anæsthetized. In skin work upon fat people it was sometimes impossible to get water anæsthesia. But in cases of hemorrhoids, the larger the better, this method of anæsthesia had proven very successful.

Dr. Edward Wallace Lee wished to corroborate all that Dr. Gant had stated. For a number of years he had resorted to this mode of producing anæsthesia in minor operations upon the extremities, and its effects he believed to be due to a paralysis of the terminal nerve filaments through mechanical pressure and also by diminution of the circulation. He had noticed where water anæsthesia had been used that there was no sloughing, such as so frequently occurred when eucaine or cocaine was used.

Dr. Elmer Lee said that in 1892, at St. Petersburg, during an outbreak of epidemic cholera, when hypodermoclysis was given it was found that the injections of water beneath the skin of the abdomen produced local anæsthesia.

Dr. Gant closed the discussion by stating that a peculiar thing to be noted was that there was practically no bleeding in these cases. Also, if you injected cocaine in one patient with hemorrhoids and sterile water in another, after the operation the first patient will jump off the table without any pain or discomfort whatever while the latter will suffer pain for hours.

The Conditions Which Interfere with Complete Success in the Operation for the Removal of the Adenoids.—Dr. Clarence C. Rice read this paper. He said the operation for adenoids was more commonly performed than any other surgical procedure and at least fifty such operations were done daily in New York City alone in the various clinics and hospitals. It was a condition always present in children with nasal catarrh, and this lymphoid tissue, or a certain degree of enlargement of it, primarily existed in children who had sore lips from their nasal discharges, who were mouth-breathers, who had catarrhal laryngitis and bronchitis, etc., and frequently this condition predisposed to pneumonia and pulmonary tuberculosis. To have to resort to surgical procedures for the removal of the adenoids added to the health and comfort of the patient. All operatians for the removal of adenoids did not always cure them, and the results that were promised failed for reasons which could be enumerated under three headings, as follows: (1) The operator did not make proper preparation for his work. He might operate too hurriedly and without anæsthetizing his patients properly, or he might have unsuitable instruments. The complete and thorough removal of the adenoids must be made before success was obtained, and complete anæsthesia should be employed. (2) The lymphoid tissue was not thoroughly removed. Dr. Rice spoke of the difficulty in clearing out the pharyngeal vault. No two cases presented similar conditions, and great care and study were necessary in order to accomplish the desired end, *i.e.* the complete and thorough removal of the lymphoid tissue. (3) The existence of abnormal conditions in other parts of the respiratory tract existing before or after operations. Dr. Rice said that our public school children, guarded by the Board of Health, were better off than the children of the rich who went about with vacant looks, open mouths, etc., and whose general health was far below par.

Dr. Francis J. Quinlan referred to the advantages of the upright position in operating for adenoids, and said that, with a competent anæsthetist, there was absolutely no danger. He said that sometimes the lymphoid tissue was pedunculated, soft, or friable, and that it was impossible at times to get rid of it either with forceps, the curette, or other mechanical device. For the last ten years he said he had used the upright position and he had had the best possible results from it. He believed that some anæsthetic should always be given. So far as hemorrhage occurring and blood going in the larynx was concerned, he had yet to see such a case. There was no possible danger of secondary trouble with the middle ear because complete drainage was had.

Notes on the Present Epidemic of Cerebrospinal Meningitis.—Dr. Henry Dwight Chapin spoke of the epidemic of this disease now present in New York City, which began early in March and which has been steadily increasing ever since. Comparing the figures obtained from the Board of Health of last year with those of the present year

he found that from March 12 to May 21 there were 64 deaths in 1903 and 498 in 1904. He then proceeded to enumerate a few of the salient points regarding this epidemic, which gave very irregular manifestations. The onset was fairly rapid. There was vomiting, chilliness or rigors, and frequently severe convulsions. The severity of the initial symptoms bore some relationship to the kind of attack. In one case a child had convulsions for four days and then made a good recovery in two or three weeks; other cases might present very mild symptoms and die. He said that if stupor or coma quickly followed the convulsions the prognosis was grave. The typical retraction of the head usually occurred on the second or third day. The rigidity was often extreme and hard to overcome. The posture of the patient was characteristic. Besides the opisthotonos, the thighs, arms, and hands may be extremely flexed. The retractions and rigidity were usually continuous during the course of the disease. The cases were very irregular in their manifestations, and those that appeared to be going on to a fatal termination recovered, while those that were very mild in type and apparently recovering would die. Dr. Chapin then considered some of the symptoms that occurred in the cases at the Post-Graduate Hospital, now under the care of Dr. Caillé. Tonic spasms of the group of muscles at the back of the neck was a constant feature. Hyperæsthesia of the skin was noted. The patients gave evidences of great discomfort when disturbed. Some cases went directly from the convulsions into stupor. Kernig's sign was recognized. Leucocytosis was present. The temperature, pulse, and respirations showed remarkable variations and gave nothing characteristic except this variability. One patient had a drop in the temperature of nine degrees in ten hours. The skin was rarely involved and no purpuric spots were noted. The eyes were more or less involved, dilating sluggishly to light. The ear was involved in a certain number of the cases, and deafness might follow. The general course and duration of the disease was very irregular. Patients extremely prostrated might go on to recovery. The most unfortunate cases were those in which the brain was affected by the disease. The diplococcus intracellulosus was obtained by lumbar puncture in all but two cases. The disease was prevalent among the poorer classes and where there were poor hygienic surroundings. He was glad to state that the coming mild weather would possibly check the disease.

Dr. Thomas R. Pooley said that both the eyes and ears might become affected in cerebrospinal meningitis early in the disease, and generally within a few days after the onset. The effect could occur in two ways, viz., by metastasis and direct invasion through the sheath of either the optic or acoustic nerve. He believed the disease more often spread along the natural nerve channels. Usually both ears were affected and with permanent results. The onset of the ear symptoms was characterized by pain and also by a persistent tinnitus and unsteadiness of gait. It was common to see one eye affected and always with complete loss of sight. Post-mortem examinations showed that the nerve trunk was involved and inflammatory condition extended to the membranous labyrinth, to the cochlea, etc., there being a purulent diffusion. This resulted in atrophy of the terminal fibers of the eighth nerve and with resulting deafness.

Dr. Wendell C. Phillips said that during the past two or three years he had made many examinations of pus in cases of acute and chronic otitis media and especially in those cases that manifested mastoid symptoms, and he had been surprised to find how many times the pus contained the diplococcus intracellularis meningitidis. This did not mean meningeal complications, but showed that the germ was present in a great many cases of acute suppurative otitis media with mastoid complication. He said that to-day at the clinics they were beginning to receive patients who lately had been victims of cerebrospinal meningitis and who now were troubled with eye and ear symptoms.

Society of Sanitary and Moral Prophylaxis.—Dr Ferd. C. Valentine regretted the absence of Dr. Prince A. Morrow, who was to make a plea for the organization of this society, and moved that such a society be at once organized. This was seconded and carried

Orleans Parish Medical Society.

At the meeting held May 28, 1904, a resolution was adopted authorizing the president and secretary to expend $5,000 for the purchase of a building for the permanent domicile. They were also authorized to issue 260 bonds of $25 each, to run twenty-five years at 4 per per cent. interest, unless retired sooner by the society, these bonds to raise the purchase price of the property and $1,500 for improvements.

After a discussion about recent "write ups" of physicians by the lay press, the following was adopted:

"*Be it Resolved*, That it is the sense of the Orleans Parish Medical Society that it is inconsistent with the highest ideals of the medical profession for members to permit the appearance in the daily press of articles bearing on their professional attainments or accomplishments."

Dr. Urban Maes read a paper entitled "Nitrous Oxide and Ether Anæsthesia." The deductions were based on 555 cases supervised and anæsthetized by the writer in 1903. Thirty-five were tabulated and the disagreeable features as well as the advantages noted. Profuse bronchorrhœa occurred but ten times out of 555. In a paralleled series of sixty cases the saving of ether was found to be 52 per cent. The dangers of reinhaling expired vapor was mentioned. The average time required to induce anæsthesia varied from three to six minutes. The extremes of age were found less suited to this method than adults. The absence of the stage of excitement was a feature especially to be commended. The method of gradual change from nitrous oxide to ether was soon found to be the best.

Dr. Quitman Kohnke, president of the City Board of Health, called attention to the fact that mistakes and disputes were often caused by the occurrence of mild ambulatory cases of smallpox, in which headache, backache, noticeable fever and malaise were absent. He had known of such undiagnosed cases in which the patients were allowed to mingle with other children at school.

Dr. Wm. M. Perkins was unanimously elected chairman of the Committee on Arrangements for the 1905 meeting of the Louisiana State Medical Society.

Investigations of Chicago Dairy Farms.—The following is a summary of the most important results of Commissioner Reynolds' personal investigation of a number of dairy farms in Illinois and adjoining States from which Chicago receives its milk supply: (1) An increasing proportion of Chicago's milk is delivered to the consumer within twelve hours after milking. The bulk of it, however, is from twenty-four to thirty-six hours old before delivery. There is no insuperable reason why it should not all be delivered within the shorter period and every effort of the department is being made to this end. (2) There is much room for improvement in the conditions of milk production on nearly all the dairy farms visited, except those under the direct supervision of a few large contracting firms. The dairy inspectors of the department are engaged in visiting this class of farms, explaining to their owners the necessary requirements, reporting upon their conditions, and recommending the exclusion of their product from the Chicago market if, after a reasonable time, they fail to conform to these requirements. (3) It costs more to produce clean milk than dirty milk—therefore, cheap milk is, *prima facie*, impure and unwholesome milk, and the housekeeper who buys it is helping to perpetuate unclean conditions of dairies and helping to swell the death rate of the city.

Books Received.

While the MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending July 30, 1904:

	Cases.	Deaths.
Measles	183	8
Diphtheria and croup	202	24
Scarlet fever	88	8
Smallpox	1	...
Varicella	11	...
Tuberculosis	341	170
Typhoid fever	83	13
Cerebrospinal meningitis	...	25

Health of European Armies.—The health of European armies has been engaging the attention of Professor Kende of Budapest, and the results of his investigation are now given to the world. Of all the armies, the professor is inclined to put the German first, though the general sanitary conditions of the French appear to be almost as satisfactory. The Frenchman, however, is of a feeble constitution. Austria, it is said, suffers from the ravages of disease, and the sanitary condition of the Italian army is most strongly condemned. Out of a thousand men, according to Professor Kende, Italy loses nine, Austria six, France five, and Germany only four. The system of Germany is certainly a good one; but it must be remembered that it is employed on a stock naturally strong and robust.—*London Globe.*

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended July 30, 1904.

THE SUCCESS OF PHYSICAL REMEDIES IN PULMONARY PHTHISIS AS AN INDEX OF THEIR VALUE IN OTHER CHRONIC DISEASES.*

BY SIMON BARUCH, M.D.,
NEW YORK.

PHYSICIAN TO HOOD-WRIGHT MEMORIAL HOSPITAL, CONSULTING PHYSICIAN TO THE MONTEFIORE HOME AND HOSPITAL FOR CONSUMPTIVES, NEW YORK.

IT were "sending owls to Athens," as the proverb says, to attempt to enlighten the physicians of this section on any subject connected with phthisiotherapy. I may, however, be able to suggest to you some therapeutic methods not in ordinary use, which have been ascertained as useful in my observations of private and hospital work. Before proceeding to the subject of the evening, I will, with your permission, Mr. President, briefly summarize some personal views on the subject of phthisis-therapy in general, and to point out that phthisis may be regarded as an illustration of what can be accomplished by systematic methodical managment in all chronic diseases. The latter have been the opprobrium of medicine because physicians have not applied the same methods of managing them which they have successfully applied in the management of acute diseases. These almost always tend to recovery or their course is sharp, short, and decisive. Chronic disease on the contrary comes upon the system insidiously. Like a thief in the night, it often invades the unguarded organism and destroys important tissue elements, when restoration is beyond our aid. In the presence of a case of typhoid fever, we begin the battle with hope and courage, feeling a certain degree of security in the knowledge that we have a powerful ally in the vis medicatrix naturæ, to enhance which all our energies are bent.

How different is our mental attitude toward chronic diseases. The modern physician who is so trustful to nature in acute disease does not feel inspired with hope or confidence in chronic disease. Far from it. Palliation is the goal of his therapeutics; restoration seems out of his reach. The average physician has certain ideas about diet in gout and diabetes, about cod liver oil, creosote and climate in phthisis, the iodides in chronic rheumatism, etc., but he cannot often lay his hand upon his heart and say that he has ever cured a correctly diagnosticated case of this kind. Why is this? The physician visits a case of typhoid fever or pneumonia once a day or oftener. He has the patient's condition recorded by nurses or relatives. His directions, medical, dietetic or otherwise are closely followed; in fact, the patient, together with his whole environment, is under his absolute control. A patient with chronic rheumatism, neurasthenia, diabetes, or phthisis, calls at the office about once a week. He is carefully examined, the history taken, the diet, etc., are ordered with precision, but from the moment he leaves the office he is no longer under the observation and control of the physician. The execution of the latter's directions depend upon his own sweet will; he returns or does not return, as directed, gives a rambling account of the effect of the treatment; the personal equation being perhaps the most important element in his statements. No skilled or unprejudiced observation of the treatment, mode of living, or anything else connected with the case is at the physician's service. The latter soon shares the patient's indifference because the danger of a fatal issue is absent, or seems very distant. The result is failure. The patient wanders from one doctor to another until at last he falls into one of the numerous quack-systems and perhaps ends with the Christian Scientist, who, by convincing him of the non-existence of the disease for which the doctors have treated him, cures at least his mind.

Such was the management of phthisis at no distant period. Happily a brighter day is dawning for the successful management of all chronic diseases, and it is entirely due to the fact that the medical profession has come to realize that phthisis, which was at one time regarded as the most incurable of all chronic diseases, has proven amenable to successful treatment. According to reliable authorities, healed tuberculous foci, encapsulated or calcified, are found in every third or fourth body examined at autopsy. Koeniger reports, from the Home for Invalids and Old People in Hanover that 58 per cent. recovered out of 591 cases of tuberculosis received there for treatment. Many colleages whom I have met here are marvelous examples of what your climate has accomplished. It would seem fair to conclude that in those cases in which healed tuberculous lesions were found without previous history, the organism had furnished all the remedial agencies necessary for the cure. The modern method of managing phthisis is really an approximation of the latter, inasmuch, as it aims to place the organism in the most favorable condition to throw off disease. I hold that the chief merit of the modern successful management of phthisis lies in the adoption of the methods long so successfully pursued in acute diseases. Constant, unremitting attention to every detail of the patient's mode of life, his environment, food, drink, rest, exercise, baths, clothing, occupation are the only road to a favorable result. Even in the matter of climate, the abandonment of indefinite ideas in favor of a more methodical adaptation of conditions existing in each, has wrought favorable results. Simplicity is here as fruitful as it is in all therapeutic questions. It is now recognized that the climate which affords the patient the largest opportunity of breathing dry air free from vitiated matter—is the most useful climate. While other elements, such as altitude, freedom from winds, rains, barometric and thermometric conditions are important, absolute purity of air and the possibility of utilizing it at all times and without

*An address before the Los Angeles (Cal.) County Medical Society.

interruption are the chief points. This is the kernel of rational climato-therapy.

In my student days most phthisical patients were sent to the South; semi-arctic regions like the Adirondacks or Davos, were regarded by our forefathers as absolutely detrimental, if not fatal. To-day many consumptives find relief and cure in the cold dry air of mountainous New York and distant Colorado, in the dry and yet bracing air of Southern California, in the moist and warm atmosphere of Florida, or in the arid deserts of Arizona.

Just as in surgery, the discussions of the comparative merits of sublimate, iodoform, and carbolic acid has become of secondary interest, since we recognize that the triumphs of modern surgery are due to strict asepsis, so has the contention about climate become of secondary interest, since we realize that methodical treatment under conditions which afford the patient the best opportunity for out-door life and air that is free from contamination and excessive moisture, are the curative factors. After all, the chief benefit of a climate lies in its judicious adaptation to each case. The celebrated health resorts of Germany, which attract a multitude of people, more or less afflicted with chronic diseases, do not owe their well-earned reputation so much to the climate and chemical composition of the waters or other local conditions, as is generally supposed. These useful therapeutic elements would be absolutely inefficient if their application were not directed by the medical men residing in these resorts, who have made it a life study to investigate the climatic and balneological advantages of their respective springs, and have convinced their confrères in all parts of the world, by conscientious striving for the welfare of the patients committed to their care and by the intelligent application of their respective local advantages, and by close attention to and guarding of the sanitary arrangements of the springs. It is really more important for the physician who sends his patient to health resorts or springs to know the mental composition of the doctor than to know the barometric characteristics of the climate or the chemical composition of the waters. As an example, let me cite the recent marvelous growth of Nauheim as a resort for cardiac cases, which is due to the studies of Dr. Theodore Schott, and his conscientious selection of cases adapted for the Nauheim waters. By scorning mercenary methods, unfortunately prevalent at many resorts, he has builded better than he knew, for the town of Nauheim has since his death become the Mecca of patients from all parts of the world. It will retain its well-earned reputation so long as its physicians will utilize it judiciously, select the patients with care and firmly decline to retain cases not adapted, though the material interests of the resort may seem to suffer.

Permit me to apply this example to Southern California. My observations since my visit here convince me that Southern California possesses in the highest degree every element for the successful management of phthisical patients. You have, according to Dr. Norman Bridge and others, low altitudes and high altitudes, dry bracing air with a mild atmosphere, and small relative humidity, a larger number of clear days than are recorded of any other health resort in my knowledge. You have much to interest and occupy the patient and thus divert his mind. Your beautiful orange groves, tropical palms, your orchards and vineyards, your cañons, your mountain scenery, the social and educational facilities—all conspire to woo the sick man to health, and, unlike more rigorous climates, to furnish pleasant and profitable occupation after he is restored and needs a favorable environment to prevent relapse. The air sweeping over desert and ocean must be pure and free of all contamination; even high atmospheric temperature appears to be free from that relaxing effect which is observed in the more humid regions of the South and East. I had, a few days ago, a personal experience which is more convincing than would be all the barometric and thermometric data I could obtain. With the temperature at 80° F. and clad in a warm suit, I was compelled to rush from street to street, in order to find some reliable information about the medical school at which I was to lecture at eleven o'clock. If I had been subjected to the same amount of mental and physical exercise in the sun of New York City, my heavy clothing would have been saturated, and I would have been exhausted. The fact that I was free from the latter was a pleasant surprise. It was a clinical demonstration of the inocuity of high temperature, in this climate. May I venture to suggest to you that you emulate the example of Schott of Nauheim, that you continue to study and investigate the grand facilities at your command in this favored section, and that you apply them with wisdom and with a conscientious regard for the patients entrusted to your care by colleagues from the North and East. Thus and thus only will the climate of Southern California attain the high repute to which it is entitled as a health resort.

It was a pleasant surprise to me to note that you have in your midst a small but model institution for phthisiotherapy which deserves to be developed into enormous proportions, if the lines upon which it has been inaugurated can be continued. It is the only private eleemosynary institution in which I have enjoyed the satisfaction of seeing hydrotherapy scientifically, judiciously, and successfully applied in phthisis, and which may be taken as a model of perfect construction.

I had been somewhat prejudiced against the climate of Southern California by statements of the tremendous fogs which are said to infest this section. Personal investigation has revealed the fact that these fogs are a blessing in that they furnish moisture to the arid soil, and at a short distance from the seashore they can do no harm to the phthisical patient, aside from the somewhat depressing effect on some patients, because of the moisture which they furnish which renders the air more tolerant to irritated lung surfaces. They also furnish moisture to the arid soil, and thus prevent dust to a great extent. Inasmuch as the fogs are usually dispersed during the early morning hours, and the air, as a rule, is entirely free from them during the remainder of the day, I cannot conceive any harm from them. The slightest precaution of covering the open resting places of the patients during the fogs will preclude any danger in acute cases, and avoidance of exercise during their brief existence will protect others.

Colleagues of Los Angeles, permit me to direct your attention to a serious responsibility which rests upon you. To you, more than to any other of its citizens, is entrusted the future prosperity and development of this garden spot of the earth. If this section is ever to attain its grand destiny, not only as a life-giving refuge for the invalid, a haven of rest for the weary, the infirm, and the aged, also as the home of enterprising men and women, who will surely discover its vast agricultural, horticultural, and other resources, *you* must see to it that strict sanitation is maintained in the

country districts as well as in the towns, but especially in the latter. I need not remind you of the patent truth, that the drainage, sewerage, water, milk, and food supply need to be watched assiduously, and with jealous care. The enormous population which is certain to be attracted at no distant day to this land of eternal spring, unlimited fertility, and inexhaustible material resources, will surely contaminate this dry and porous soil with disease germs, which the rains will as surely pour into your springs, wells, and water-courses, unless the sewerage is carefully watched and guarded from its source to its discharge, step by step, without interruption. Only in this manner will it be possible, as you are well aware, to segregate it from contact with the drinking water. There must not be a shadow of doubt or suspicion. Eternal vigilance is the price of health and prosperity as it is of liberty. To the physician and sanitarian is committed the unappreciated but noble task of safeguarding the priceless treasure of health of every community, against the rapacity of political jobbers and others whose soul is encased in their bank accounts, and who would fain diminish the tax levy by penurious appropriations to the health department. You and I know that no expenditure of public funds is more economical and profitable to a community than the money spent for sanitary purposes.

Hydrotherapy.—Any doubt that the subject of hydrotherapy demands more frequent discussion would be removed by the interest with which my humble labors on this subject have been received by the wideawake, intelligent, and progressive colleagues whom I have met here. The eagerness and earnest attention with which the subject has been discussed at the various functions at which I have had the honor to be entertained, and the evident desire for more exact information which the requests of the officers of your medical societies and of the faculty of your school have evinced, have been a delightful revelation to me, and will stimulate me to renewed effort. In addition, a glance at the Transactions of the American Climatological Society for 1901, which I happened to see in the office of my friend Dr. Barlow, assured me that I would be recreant to my duty if I failed to respond to the several requests for addresses on hydrotherapy, which have been made since my advent in this community. The president of the American Climatological Association for 1901, Dr. Babcock, deplores the absence of papers on hydrotherapy, and pleads for deeper interest. "Water," he says, justly, "in its various forms of administration is so powerful an agency for good in a large number of chronic disorders, that a series of contributions upon the subject ought to prove both edifying and interesting. So numerous have been contributions to the subject of tuberculosis that it has been said, with some show of truth, that we are in danger of becoming a society of tuberculosis rather than of the broader scope originally intended. This is natural, owing to the absorbing interest and universal importance of this class of diseases. Is it not singular that we have had no discussion upon the use of cold in the treatment of pneumonia and pleurisy, for instance? To my mind cold in the form of baths or ice is so valuable in these affections, both for the antipyretic and analgesic, and for the tonic effect on the nervous system, that its employment by the rank and file of the profession is altogether too much neglected."

In an excellent article on "home treatment" in the same number of the transactions I find precise directions given for the dose, preparation, mode of administration of creosote, of acetanilid, phenacetin, antipyrin, codeine, and other medicinal agents. When, however, the author, who evidently understands well the principles of hydrotherapy, writes of the latter, he becomes vague, and the confidence he expresses in his medicinal therapy vanishes. He says, "In the acute febrile stage the patient is sponged with alcohol and water three times daily, and his linen changed as often as required; when he has improved and become convalescent, he is advised to take a cool sponge bath every morning, standing in a rubber tub before the washstand that has a large basin full of cold water on it ready for use, and a big linen sheet for drying by the side of it. Time allowed for this procedure, from two to five minutes." He fails to state the proportion and temperature (dose?) of alcohol and water; and allows the reader to guess the temperature of the "cool" sponge bath. He errs too, in ignoring the fact that when a patient with feeble reaction stands in a tub and has "cool water" running over him, he will soon stand in a puddle of cool water, he will be chilled, and have his reaction lowered.

I am glad to find in another article on "home treatment" in the same volume that this point is recognized by the author, who I am proud to acknowledge as one of my earliest disciples.

Before proceeding to the technique of hydrotherapy in pulmonary tuberculosis it is meet that we consider briefly the principles upon which water of a temperature below that of the skin (and this is my standard for cool and cold water) acts on the human organism. It would be an insult to your intelligence to presume to offer you formulæ without pointing out the reasons underlying them. The principal effects of cold water externally applied are traceable to reaction which follows the shock to the minute nerve and vessel terminals in the skin. There are many laboratory experiments to prove that the irritation produced by cold is conveyed on sensory tracts to the brain and spinal cord, and thence reflected on motor tracts upon the organs which receive functionating capacity from this central "powerhouse." This is clinically illustrated by the gasp of a still-born infant when it is sprinkled with cold water. I have termed this "nerve reaction." When cold is applied to the skin the arterioles and capillaries contract, as is well known. If the cold is continued, as in the application of the ice-bag, the arterial blood is driven into the deeper vessels, while the blood of the veins, which have no muscular support, is retained; stasis ensues, as is evident from the dark red and cyanotic hue of the skin. If the application is brief, the blood driven to the deeper parts returns quickly to the surface and the skin becomes pink. In the latter case there is a stimulation of the vasodilators, in the former there is an overstimulation, which temporarily paralyzes the vessels. To evoke a proper reaction, *i.e.* to adapt the application of cold to each case, demands care and judgment. But the latter may be guided to a sure and definite course by observing the principles here rather briefly enumerated. Brief applications of cold stimulate, longer applications depress, and prolonged applications destroy vitality (frostbite). Moreover, we have four methods of dosage in the application of water, whereas we have only one for medicinal agents. (1) The temperature, (2) duration, (3) force, and (4) technique. These are well illustrated in the management of the still-born baby. In a mild case simple sprinkling with water, about 75° F., suffices; in a severe case the "dose"

is increased by a brief dip of the whole body into water, and may be intensified, as you know, by alternately dipping into warm and cold water. The sprinkling is a miniature douche, the dip is a miniature bath, the alternate use of hot and cold is often adopted in feeble phthisical cases, as I shall show. The principle involved (peripheral irritation) is the same in all procedures.

You will perceive, therefore, how irrational it is to order a patient to take a cold wash or a cold bath without stating temperature, duration, and mode of procedure. Sprinkling with cold water may suffice to restore an asphyxiated infant; it will be ineffectual in a case of typhoid fever, which requires a more prolonged application (a larger dose)—a cold bath. The latter would be as much too large a dose of hydrotherapy for the infant as the former would be too small a "dose" for the typhoid case. Let us be precise, then, in our directions. Inasmuch as the object of all cold procedures is to evoke reaction, in proportion to the reactive capacity of the patient, the nature and stage of the disease, etc., it follows that he who best understands the principles of hydrotherapy will succeed best in the application.

What are the indications for hydrotherapy in phthisis? (1) To increase blood cells and hæmatosis, (2) to deepen inspiration, (3) to enhance nutrition, (4) to eliminate excretory products, (5) to remove stasis, (6) to reduce temperature.

1. It is the vaunted merit of altitude that it increases blood-cells and enhances hæmatosis. It has been clearly proved also that all judicious general cold applications to the skin increase the white and red cells and hæmoglobin from 10 to 25 per cent., and that this is due to the tonic dilatation of the cutaneous (and all peripheral) arterioles, which aids in propelling the blood more actively onward, and at the same time offers a more normal resistance to the blood driven forward to the heart and reduces a rapid to a more nearly normal pulse. The cause of corpuscular increase due to altitudes is quite different, as shown by the experiments of Mosso, who, in "Life of Man on High Alps," p. 187, concludes correctly that "The rapid changes in the pulse observed during ascents, and more especially during mountain sickness, are due to the state of the blood-vessels. When these dilate, the resistance opposed to the circulation of the blood is diminished, and the heart beats more rapidly." You will perceive the vast superiority of hydrotherapy over altitude for purposes of blood-cell improvement—a superiority which is emphasized by the accessibility of the one and difficulty of attainment of the other. Without entering into more details to which I am tempted, it may be held that the daily exercise of the cutaneous blood-vessels and nerves, during and subsequent to a judicious cold procedure, is really a neurovascular training, which affords the patient the same physiological benefits that muscular exercise offers, and the same advantage that altitude offers without the occasional defects of either in many cases.

2. The deepening of the respiration is a legitimate effect of all cold procedures, as Winternitz, myself, and others have demonstrated by experiment. That the larger surface for oxygenation of the blood and elimination of CO_2 thus afforded, which is increased by the greater dilatation of the peripheral vessels in the air cells, must redound to the patient's benefit, need not be impressed upon you.

3. In the enhancement of the nutrition, the improvement of the circulation and respiration is, as you are aware, a potent factor, but there is an additional factor that comes into play in the effect of stimulation of the skin nerves upon the brain and sympathetic. The refreshment of the latter serves to heighten the appetite, improve the digestion and assimilation, and thus to increase nutrition as no other agent is capable of doing. In the Montefiore Home the increase of weight and improvement in the appearance of patients has been striking.

4. In all infectious diseases there is an increase retrograde tissue change, and owing to the sluggish circulation in the glands there is a defective oxidation and consequent retention of the products of tissue change. The enormous increase of well-oxygenated blood, resulting from cold procedures, enhances glandular action and serves to diminish and often entirely to remove this serious condition which slowly conduces to a fatal issue.

5. Removal of stasis. In all infectious diseases the brunt of the disease falls upon the circulation, to the failure of which the final issue is often due. Stasis in the vital organs cripples the secretory, excretory, and assimilative functions by which life is sustained. We have no medicinal agent which even temporarily removes capillary stasis, except from valvular insufficiency. By the judicious adoption of the cold procedures, which I shall refer to, stases are removed, by reason of the tonic effect upon the cutaneous and consequently also upon all peripheral vessels. Dr. Barlow can doubtless show you, in his sanatorium, how the cyanotic finger nails and lips of phthisical patients assume a pink and ruddy hue after one of his properly applied cold plunges. If you witness this once only you will require no further argument to convince you that stases are readily removed by hydrotherapy, judiciously applied for reaction.

6. Reduction of temperature. I have intentionally placed this action of cold water last, because, contrary to the generally accepted view, it is the least potent of all the effects. Nevertheless it is more valuable for the relief of this distressing symptom than the highly vaunted coal-tar products, whose chief advantage appears to be that they enable the patient to die with a nearly normal temperature. An ablution or bath with water below the temperature of the skin may not reduce temperature so readily or efficiently, but it accomplishes the result less violently, not only without cardiac depression, but with cardiac invigoration and general refreshment.

Though these general therapeutic truths have necessarily been briefly stated, their application in phthisis will, I trust, be clear. The flexibility of hydrotherapy enables us to devise procedures for every stage of phthisis pulmonalis. Nevertheless the most useful general method will prove to be that which aids in gradually accustoming the skin to lower temperature, greater pressure or mechanical force, and larger quantities of water—in all stages.

The most useful method* in subacute cases will be attained by gradually accustoming the skin to lower temperatures and larger quantities of water, always bearing in mind that reaction, indicated by a feeling of comfort and absence of chilling effect, must be obtained. In febrile cases low temperature applications are contraindicated. Here the ablution, or a half bath with water not below 80, is indicated. When temperature reduction is desired in febrile conditions, the absence of reactive capacity in these patients forbids procedure of low temperature or long duration—a fact too often disregarded to the discouragement of the physician.

My observations at the Montefiore Home and Hospital for Consumptives, in which cases of the

*"Principles and Practice of Hydrotheraphy" (p. 383). Wm. Wood & Co., 1904.

most forlorn types are received, have led me to adopt the following mild and graduated course:

After a thorough cleansing with soap and warm water, a day is allowed to elapse. The patient is wrapped snugly in a thin blanket like a mummy (unless rectal temperature is above 100°). He is allowed to lie for half an hour or longer unless he perspires. In afebrile cases it may be necessary to cover with additional blankets, the object being to fill the cutaneous arterioles, preparatory to being treated with water. The face is bathed with water at 50° F. Now the blanket is opened over the chest and abdomen, and these parts are rapidly and well rubbed with water at 75° F. After drying, the patient is turned on the abdomen and the back is similarly treated. The extremities are not treated. Patient is gently dried, dressed, and if afebrile, ordered into the open air for a gentle walk. Febrile cases are returned to bed. This treatment is repeated daily with reduction of two degrees of water temperature at each ablution until 60° F. are reached. Now the ablution is performed just as the patient emerges warm from the bed, as follows: Standing in a foot-tub, containing sufficient water at 100° F. to cover the feet to the malleoli, he receives a rapid friction bath with water at 90°, omitting the upper extremities, after which he is dried and sent into the open air, if his rectal temperature is below 100° F. The water temperature is reduced daily two or five degrees until 60° F. are reached. Now the ablution is replaced by affusion, which consists of pouring of four basinfuls of water at 90° F., previously held in readiness, over the body. The patient standing in a foot-tub, having the feet covered with water at 100°, water is dipped from a vessel previously in readiness and poured with force over each shoulder and back and chest. Rapid drying while standing on a warm towel completes the procedure. Beginning with a water temperature at 90, it is daily reduced a few degrees until 60° or even 50° are reached. This refreshing process may be repeated daily. In febrile cases the water temperature should not go below 65°.

Other methods, as chest compresses in febrile conditions, and fan douches in subacute cases, are described in works on hydrotherapy, so that I need not here refer to them at length.

The principle involved in all applications of water below the skin temperature is the sudden (so-called) shock, the reaction and subsequent refreshment due to the reflex effects arising from the excitation of the sensory terminals and arterioles of the skin.

I shall not weary you with clinical demonstrations of the value of these simple procedures. The records of the Montefiore Home and of my private clientele abound in them.

In conclusion, let me urge upon you to become more familiar with hydrotherapy in phthisis and other chronic diseases through the gentle, mild, and harmless procedures here briefly indicated.

Hotel Majestic.

Bathing in Japan.—Clarence Ludlow Brownell, in his recently published book, "The Heart of Japan," says that the death rate for children is lower in Japan than it is in Europe and in America. This is as it should be, in a country where the houses are off the ground a foot or two, and have no cellars, and the air inside is as fresh as it is out; where, too, in such places at least as Tokio, every one bathes and has a good scrubbing every day. From 800,000 to 1,000,000 persons go to the public baths of the capital daily, and there are tens of thousands of private baths besides. That is a good showing for a city with a population of less than 2,000,000.

CEREBROSPINAL MENINGITIS, WITH REMARKS ON ITS DIAGNOSIS, PROGNOSIS, AND TREATMENT.*

By LOUIS FISCHER, M.D.,
NEW YORK.
VISITING PHYSICIAN TO THE WILLARD PARKER AND RIVERSIDE HOSPITALS.

The recent epidemic of cerebrospinal meningitis, which began in the early winter and which has continued throughout the spring, has afforded a large field for study.

I shall give a résumé of cases seen in my own practice and of those seen in consultation practice, for they cover the most important diagnostic and therapeutic points.

This disease was first described in America in 1809, although we owe its first clinical description to Vieusseaux of Geneva, in 1805. The disease exists in the beast as well as in the human being. It is caused by the entrance of the diplococcus meningitidis. The systemic symptoms, such as spasms of the muscles of the head and neck, are undoubtedly caused by a virulent poison or toxin generated in the body by the diplococcus. The paralytic symptoms compare very favorably with that serious toxæmia with which we are well acquainted, associated with diphtheria.

Bacteriology.—The presence of the meningococcus intracellularis, also called the diplococcus meningitidis, has been demonstrated by Jaeger[1] and Weichselbaum in 1887. Their results have been corroborated by Heubner[2] and by Finkelstein,[3] and by Baginsky of Berlin. In this country by Councilman.[4]

The diplococcus is found within the cells (intracellularis) chiefly in the polynuclear leucocytes. It is seen in pairs and tetrads. The arrangement of the germ under the microscope resembles that of the gonococcus. In some cases there is an infection by the pneumococcus and by the streptococcus. These cases are usually fatal.

The presence of the pneumococcus easily explains why pneumonia is so frequently associated as a complication.

The purulent discharge from the eyes and the nasal secretions from the patients so affected have been found to contain the diplococcus. It should be borne in mind that under normal conditions the nose harbors a germ which resembles morphologically the diplococcus meningitidis. Heubner demonstrated the diplococcus to me from the nasal discharge of a child so affected at the Children's Hospital of Berlin in 1899. A smear taken from the pharynx and tonsils in two of my recent cases suffering from this disease did not show the presence of the diplococcus.

It is quite possible that the germ enters the body through the various lymph channels, in addition to entering directly through the circulation. The diplococcus meningitidis is usually found in the spinal fluid taken from a case of meningitis during life. It has also been found in the pia mater, and other portions of the brain, post mortem.

The bacteriological examination should be made by the examination of the spinal fluid, by means of a lumbar puncture. Councilman says: "Too much cannot be said of the importance of spinal puncture in making the diagnosis. As a diagnostic measure it ranks in value with the examination of the sputum. A microscopical and bacteriological examination of the fluid should always be obtained in order to ascertain what organism is present. In no other way would it be possible to arrive at certainty with regard to the nature of the sporadic cases. We believe that all infections of the meninges other

*Paper read before the Harlem Medical Association.

than by the diplococcus are fatal, but this can only be determined by microscopical and bacteriological examination of the exudation obtained during life by spinal puncture. If tubercle bacilli, pneumococci, or streptococci are found with the evidence of meningitis in a case which recovers, it would settle the

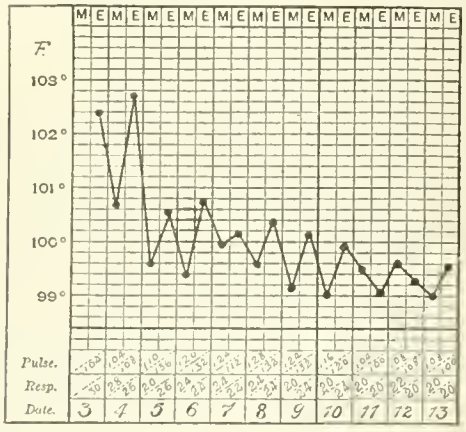

Chart 1.—Cerebrospinal meningitis; Case I, recovery.

point. Clinical evidence without a spinal puncture will not."

The space between the third and fifth lumbar vertebræ is usually chosen as the site of the puncture. The child is placed on its right side with the spinal curve toward the operator, in this way spreading the vertebræ so that the greater angle formed by the vertebræ is toward the operator. In this manner the vertebræ are approximated on the anterior surface, and are separated on the posterior border. When inserting the needle in this position there is less risk of introducing the point into the vertebræ or into the side of the canal. In making a puncture we should use a needle such as would be required in making a puncture for empyema. The needle should be pushed a little upward and forward, then the stilet should be withdrawn. If the fluid does not escape through the needle, withdraw it slightly and reintroduce the stilet to dislodge any obstruction in the caliber of the needle. A dry tap may result from the needle being obstructed with fibrin. Make the puncture as simple as possible, rather than lacerate the tissue around the vertebral column, and cause bleeding by lateral movements of the needle.

Locally, ethyl chloride, in the form of a spray or ether, might be used in a very sensitive child. It is not necessary to have a profound general anæsthesia during this procedure. General rules of asepsis must be strictly applied to the child's skin, the operator's hands, and the needle used.

In most cases in which lumbar puncture was made 20 to 30 c.c. of fluid is withdrawn. When fluid is withdrawn for diagnostic purposes then a small quantity, 10 to 15 c.c. will suffice.

When tapping the cerebrospinal canal the usual method of strict asepsis must be employed. In spite of this, various writers have reported severe hemorrhages. In two of my cases severe vomiting was produced after the puncture was made.

Symptoms.—A sudden onset occurs with acute manifestations. In young infants this disease is usually ushered in with convulsions, in older children a chill may precede the attack. Later on we have vomiting, pain in the head, frontal or occipital, at the base of the brain and back of neck, moaning, delirium, and opisthotonos. The kidneys functionate properly, sometimes there is enuresis. Retention of urine is a frequent symptom. The tendons are very sensitive on the slightest pressure. The skin feels hot and frequently is covered with a rash of a dark bluish color, resembling purpuric spots. From the presence of the rash the disease is called "spotted fever."

The temperature ranges between 100° and 105°. Some authors report temperatures as high as 107° and 108°. The pulse varies. It may be slow, or very rapid. The breathing is regular in some cases, while in others there is a distinct Cheyne-Stokes respiration. Constipation or diarrhœa may exist. The appetite is invariably poor. Vasomotor disturbances, such as the flushing of one ear or cheek, are occasionally seen.

On stroking the chest with the finger nail, a red mark is frequently noted, the tache cérébrale. The patellar reflexes are usually absent; the plantar reflex is occasionally seen.

When the sole of the foot is irritated, there is a strong hyperextension of the big toe (Babinski's symptom). This symptom is not always present. It is found more frequently in tuberculous meningitis. It is also frequently noted in perfectly healthy children. I have found it in forty out of fifty healthy children in my clinic.

When the thigh is flexed on the abdomen and we try to extend the leg, there exists considerable latent contraction, the so-called Kernig's sign. This symptom cannot be depended upon. Lumbar puncture reveals an *opalescent* fluid containing the meningococcus. The piercing cry described by the French as the cri hydrocephalique is never present in epidemic cerebrospinal meningitis.

In a case of mine recently seen, a purulent conjunctivitis was followed by opisthotonos, spasm of the sternomastoid, general rigidity of the extremities, and high fever.

Flexner and Barker studied the blood in fatal cases and found a marked leucocytosis. Neither the Babinski nor the Kernig sign nor the blood should be relied upon alone in making a diagnosis.

The Joints: The joints are frequently swollen and simulate rheumatism, but the presence of the meningeal symptoms will easily differentiate this condition from rheumatism.

Eye Symptoms: Strabismus is frequently present. In some cases there is nystagmus. The pupils are unequally dilated, and there is marked photophobia. Photophobia is frequently present. In one of my cases the child cried whenever the light was brought

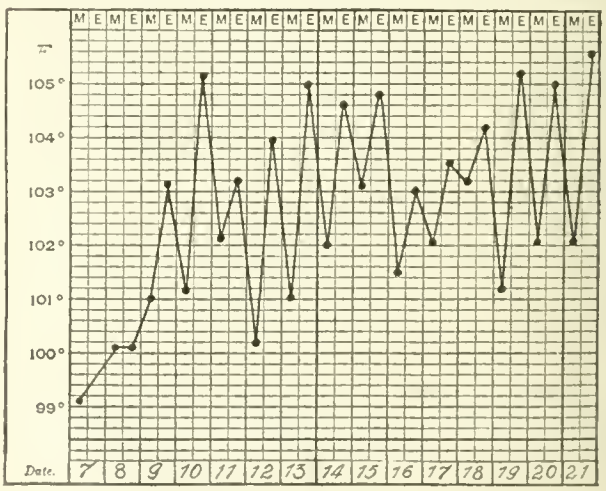

Chart 2.—Malignant cerebrospinal meningitis; Case III.

near it. The above case occurred in the practice of Dr. E. D. Lederman.

Mortality.—The mortality has been exceptionally high this winter. It has ranged between 40 and 70 per cent. in some of the larger hospitals of this city. The mortality in private practice has been equally

high. Out of twenty-one cases seen by me there were fourteen deaths. In one case death occurred twelve hours after the first symptom was noted. Other cases were comatose and lasted as long as fourteen days.

There are two types of this disease most frequently seen first, the mild type, also known as the abortive type; second, the malignant type, also called fulminating type.

Case I.—Malignant type; recovery. Sequela, deafness. Albert E. S., aged three years two months, had been in perfect health until March 18, 1904, when fever developed, with headache and explosive vomiting. The child was placed in bed and given a cathartic. The symptoms increased in severity and the mother sent for Dr. H. Frank. He found the child unconscious, delirious, and moaning. There was opisthotonos and dilated pupils. The convulsions continued, and on the second day a purpuric eruption appeared on the chest and back, but not on the face. I saw this case in consultation with Dr. Frank on the third day of illness. The child was rigid and the symptoms previously described were increased in severity.

A lumbar puncture was made and about 45 c.c. of a turbid (milky) spinal fluid was withdrawn. This fluid showed the characteristic meningococcus. The child convalesced. A very unfortunate sequela —namely, total deafness remains since this illness. The child was referred to Dr. H. Jarecky for an examination of the condition of the ears. He reports the prognosis hopeless, saying, "in all probability the inflammation has spread along the acusticus or through the aqueducts of the labyrinth where the purulent process has been followed by tissue destruction. Both membrana tympana are normal." Deafness will probably be permanent.

Case II.—Malignant type, fatal. On April 3 I was called to see a child about three years old in consultation with Dr. M. Kleinman. The child was well on Saturday morning, but later complained of headache and vomited. The attending physician found a temperature of 103°, pulse 100, irregular. Several hours later he saw the boy with dilated pupils and comatose. The temperature was subnormal, the pulse 60 and irregular. Small, hemorrhagic spots appeared on the skin. When I saw this case in consultation the above symptoms were increased in severity. Marked rigidity of the sternocleidomastoids was noted and convulsions were constantly present. The case ended fatally in less than twelve hours from the beginning of the attack.

Case III.—Seen in consultation with Dr. L. F. W. Haas on April 19, 1904, to whom I am indebted for the following history: "Rosie H., aged nine years, had been well up to the time of her present illness. It began with chills and vomiting and headache. She soon became comatose. This stupor lasted for a day. The fever continued. From the history the child went through a pneumonia. On the seventh day I was called in again. Found the child in a state of collapse, pulse weak and rapid, hardly perceptible. Temperature about normal, extremities cold, lips and nose blue. Gave hypodermics of strychnine and whiskey, which revived the child. Could only find harsh breathing on right side upper lobe (harsher than normal), with a few moist râles. Cough was present."

When seen by me the body of the child was rigid, especially the sternomastoids. The child moaned continuously. The patellar reflexes responded slightly. There was a distinct Babinski phenomena. The pupils were unequally dilated. The child was in a deep coma. The pulse was small, very rapid, and at times intermittent. The breathing was labored and at times of the Cheyne-Stokes' type. The temperature was 105°. The body was extremely emaciated and had a distinct typhoidal appearance. Owing to the emaciation, decubitus (bed sores) were present. The tongue was coated. The throat was examined without difficulty. Lumbar puncture was not made. The clinical picture was very evident. The child died in the fourth week of illness.

Case IV.—Mary M., eight years old, complained of headache while at school and was sent home. She vomited and complained of her eyes. She had a slight yellowish, purulent discharge on the inner canthus of the left eye. That same night she was unconscious and had twitchings. Her mother sent for the doctor, who diagnosed meningitis. She had strabismus, uneven pupils, photophobia, spasm of the sternomastoid, and pain on palpation at the base of the skull. There was a hemorrhagic eruption visible on the chest and abdomen. A flush on one cheek (vasomotor disturbance) was visible. On the following day the temperature was 105° in the rectum. The child moaned continuously, especially when touched. She died on the fourth day of illness.

Case V.—Abortive Type. One week later Geo. M., two years old, a brother of the child just mentioned, showed signs of irritability and restlessness. He had no appetite, and when coaxed to eat he gagged and vomited. There was no cause for gastric disorder. The temperature taken in the rectum was 102°, pulse 118, respiration 30. There was a slight photophobia. The conjunctivæ were injected. A dose of calomel was administered and a mustard foot bath given. The diet was regulated and the child was apparently well in four days.

Sequelæ.—The most frequent complication is deafness. (See clinical case of Albert S.) Such cases may end in deafmutism, blindness, epilepsy, hemiplegic conditions, and typhoid fever. A case of this kind which developed symptoms of typhoid fever during the apparent convalescence of cerebrospinal meningitis was seen by me in consultation with Dr. N. Mandelstamm. This attack of typhoid fever followed sixteen days after the first sign of meningitis.

Prognosis.—The prognosis is usually very grave, and depends on the vitality at the time of the beginning of the attack. If a case recovers, deafness or some serious sequelæ may cripple the child through life.

Treatment.—Dietetic Treatment: To sustain life we must feed the child. The gastric irritability and tendency to vomit can be overcome by rectal feeding of peptonized milk or peptonized yolk of egg. Gavage should be resorted to and light nutritious food, such as whey, white of egg, soups, and broths, should be given at regular three or four-hour intervals.

Place the child in a room having a temperature of 68° to 70° if possible. If high fever is present, shave the scalp and apply an ice-bag on the top of the head and at the nape of the neck. A mustard foot bath will, in some cases, relieve the cerebral symptoms. Tub baths (tepid) may be tried. The cold pack or ice-water coil has a very soothing antithermic effect. When delirium is present, a few leeches applied over the mastoid will sometimes afford relief.

The bowels and kidneys must be carefully watched. Retention of urine requires supervision. If the urine is scanty we can stimulate the same by giving high colon flushings of normal saline solution at a temperature of 110°.

Medication: The hypodermic injection of $\frac{1}{30}$ of

a grain of morphine sulphate should be repeated three times a day or oftener until the child is quiet. In some cases five or ten drops of spirits of chloroform given with the food every three or four hours is beneficial. Ten-grain doses of sodium bromide can be given every three or four hours until the cerebral symptoms are modified and the child is quiet. As most of the antispasmodics are cardiac depressants, the pulse requires careful watching. The inunction of silver ointment along the spine, at least fifteen minutes at a time, can be tried and repeated several times a day. Injections of lysol into the spinal canal were not used by me. If stimulants are indicated then tr. of musk or the hypodermic injections of camphorated oil or black coffee are indicated. Hyoscyamia tablets of one-hundredth of a grain are useful when active delirium is present.

Suppositories containing 10 grains of chloralamid, with or without small doses ($\frac{1}{8}$ grain) of belladonna, is a useful sedative and promotes sleep.

Large doses of iodide of potassium or sodium iodide 1 to 4 gms. (15 to 60 grains), or even more daily, may be tried. I have tried iodoform collodion, 10 per cent., over the scalp and nape of the neck in three cases of the recent epidemic without any appreciable result. Mercurial ointment, rubbed into the scalp and nape of the neck morning and evening, was used in a case that recovered.

Corning recently devised an instrument for injecting medication into the spinal canal. The tube is to be inserted through an incision made along the side of the spinal process of the fourth lumbar vertebra. The tube is left permanently in place for days or weeks. Through this silver tube a fine needle, attached to a glass syringe, can be pushed through the membranes (the dura and the arachnoid). In this manner the subarachnoid space can be medicated.

Browning of Brooklyn reports a case sent to the Bushwick Hospital, in which an operation was performed at the occipital site. It was believed that more prolonged and effective drainage could be obtained by this method. Following surgical teachings, he drained off as much infectious material as possible. The reason for selecting the occipital site for the operation is because it lies directly opposite the foramen of Magendie, which is the ventricular outlet of the fluid. Here also there is less chance of return infection.

Brain surgery has not yet given anything but temporary relief. Our only hope lies in the discovery of an anti-meningoeoccus serum.

Suprapubic Prostatectomy.—Wiener concludes that (1) Suprapubic prostatectomy can be rapidly and safely performed under laughing gas. (2) Any patient who can stand laughing gas for ten or twelve minutes can have the operation performed. (3) Old age, diabetes, and cystitis are no contraindications. (4) All of the contraindications usually mentioned are contraindications not for the operation but for the administration of ether or chloroform. The value of laughing gas and of rapid work in these old prostatic cases cannot be overestimated. These two factors are, we believe, the keystone to success in suprapubic prostatectomy. Few, indeed, are the patients, even though eighty years of age, or suffering from diabetes or sepsis, that cannot be entirely cured.—*Journal of the American Medical Association.*

ASSOCIATED MOVEMENTS OF THE UPPER EYELID AND LOWER JAW.

By EDWARD B. COBURN, M.D.,
NEW YORK.
ASSISTANT SURGEON AND PATHOLOGIST TO NEW AMSTERDAM EYE AND EAR HOSPITAL.

Movements of the upper eyelid associated with movements of the lower jaw are of great interest both to the neurologist and to the ophthalmologist, and because of the unpleasant curiosity which these cases excite in the public mind they usually come to the attention of the physician at an early date.

For this latter reason I was consulted for the relief of certain symptoms which are detailed in the report of the following case:

J. S., aged six, is a well-nourished boy of fair size, who presents a marked ptosis of the left upper eyelid (Fig. 1). By no effort of the will is he able to raise the lid, though by puckering his lips as though about to whistle or blow and raising his eyebrows, the eyelid is slightly raised. While simply whistling the lid is not raised. It may be raised by simple elevation of the eyebrows (Fig. 2). However, when the mouth is opened the lid is immediately raised to its maximum height (Fig. 3). In chewing, the lid opens and closes with synchronous movements of the lower jaw and reminds one of a chopping machine. When chewing food in the left side of the mouth the lid is only slightly raised; while chewing in the right side (opposite) the eyelid is as fully elevated as when the mouth is opened. So, also, movements of the jaw to the right (opposite) side cause the lid to be raised. Biting on any substance placed between the front teeth causes no change in the position of lid. The boy masticates his food very slightly before swallowing it, as he claims that his jaws get tired in the region of the masseter and pterygoid muscles. The act of swallowing is not associated with any motion of the eyelid. When yawning the lid raises. With the mouth open, protrusion of the tongue does not cause further elevation of the lid. No movement of the lid is caused by movements of the tongue in the closed mouth. The patient is not able to protrude the lower jaw very well, but in attempting to do so the eyelid is slightly elevated. Slight trembling of the lid is observed when the boy is speaking. If the right eyelid is held shut, then the left can be partially opened, and by the action of the frontalis muscle can be still further raised. When the mouth is opened the eyelid appears to be raised higher if the patient is looking down than when he is looking directly forward. He is able to overcome almost completely the opening of the eyelid by a forceful contraction of the orbicularis muscle. There is probably no motion of the eyeball during the movement of the eyelid. At times, however, the eyeball seems to move slightly downward when the jaw is lowered, but this may be more apparent than real and simply an illusion due to the motion of the eyelid. The mobility of the eye is apparently good except that the eye does not go upward as far as the fellow eye.

When the head is turned toward the affected side (left) the lid is partly raised, but remains entirely closed when the head is turned to the right. If the right lid is held shut the left can be fairly well opened, but not so well as when the mouth is opened. There is slight elevation of the lid when the chin is raised.

With Graefe's test, the left eye being covered the left eye is seen to look down and in. With right eye covered and looking with the left, the

right eye stands higher. On examining for double images they are found on the left side of the field of vision with the image of the affected eye standing higher and to the left of the image of the sound eye. The images increase in height when the eye is turned toward the left upper field. The pupils

Fig. 1. Usual appearance with ptosis and mouth closed.

are similar in size, and their reaction and consensual relations are normal.

There is no epicanthus and no apparent abnormality of the face (as facial paralysis) or marked asymmetry of the head.

Vision is R. $\frac{20}{20}$ and L. $\frac{20}{30}$. Under homatropine retinoscopy reveals R. + 4D, L. + 6D.

This condition was noticed at or about the time of birth and has continued unchanged ever since.

The boy was the third child and was born without medical or other assistance, so the lesion cannot be ascribed to traumatism other than the natural traumatism of labor. How much this factor is responsible for many congenital defects is as yet unknown. The first child had measles and died later of spinal meningitis. The second child has perfectly good eyes and is still living. The paternal grandmother and the paternal uncle were both "cross-eyed." There is no evidence of hereditary syphilis.

From this description it is seen there is correlation between the nervous impulses conveyed to the levator palpebræ (actuated by the third nerve on the one hand) and the digastric and external pterygoid muscles (supplied by the fifth nerve on the other).

Opening of the mouth is largely accomplished by the anterior part of the digastric, which is actuated by the mylohyoid branch of the inferior dental nerve, a branch of the inferior maxillary division of the 5th. The lateral movement of the jaw is caused by the action of the external pterygoid muscle, which is innervated by either the pterygoid or buccal branch of the inferior maxillary nerve. Perhaps other muscles supplied by the fifth nerve are involved, but if so their action is supplementary to the muscles already named. The slight elevation of the lid, as shown in Fig. 2, is due to the action of the occipitofrontalis muscle.

A study of the double images shows an involvement of the superior rectus and the inferior oblique, for if the superior rectus alone were involved the eye would be directed downward, whereas if the inferior oblique were the only one affected the patient would be able to elevate the eye.

Thus we see an intimate relation between the action of the trigeminus and the motor-oculi nerve, the affection involving only the digastric and pterygoid portions of the fifth pair of nerves and that portion of the third nerve which supplies the levator palpebræ, the superior rectus and the inferior oblique, leaving untouched the ciliary branches and the branch to the internal rectus muscle.

Another peculiarity of this affection is that the commissural fibers are also affected, as the levators do not act consensually.

In 1895 Sinclair attempted to collect all of the cases of this kind then reported, but evidently overlooked some. The author has been able to find others (some, however, reported since that date), but as it is extremely difficult to obtain certain foreign medical journals, dissertations, reports of societies, etc., it is not impossible that other cases have been reported which are not included in the accompanying list.

This list is made up from Sinclair's article, with cases added by the present writer. Sinclair's cases are marked. In addition to the cases mentioned above there are references in the literature to cases of Hoyges and Neiden, but the details of the cases I have been unable to obtain for classification and so are omitted.

General Description.—Upward movement of the upper eyelid associated with movement of the lower jaw. The upper lid is raised when the lower jaw is moved, but the eyelid alone cannot be raised voluntarily. The movement is limited to the upper lid (action of the levator palpebræ muscle).

Group 1.—Movement of the upper eyelid when the jaw is opened (digastric), and when it is moved to the opposite side (external pterygoid): Ptosis. *(1) Becker. *(2) Bloch. *(3) Bloch. *(4) Proskauer. *(5) Goldzieher. *(6) Schapringer. *(7) Snell. *(8) McIntosh. *(9, 10, 11, 12, 13)

Fig. 2. Attempted opening of the eye by the action of the occipitofrontalis.

Sinclair. (14) Coppez; man, aged twenty, ptosis right. Lid opens also when swallowing. (15) Coppez; girl, aged eleven, ptosis right. Operation of Gillet de Grandmont cured the ptosis. (16) Laqueur; ptosis right. Suggests Panas operation for ptosis. (17) Miller; boy, aged nine, ptosis

left. Paralysis of left superior rectus. Left pupil larger than the right. (18) Bernhardt; boy, aged nine, ptosis left. By chewing, but no change noticed when biting with mouth closed. (19) Hilleman; patient, aged eighteen. Drooping of left eyelid; also by projecting jaw. (20) Uhthoff; girl, aged nineteen. Eye (left). Diplopia looking to the opposite side. (21) Von Reuss; patient, aged eighteen, ptosis left. Affected eye opened when sound eye was closed. (22) De Wecker; woman, aged twenty-three, right ptosis. (23) Coburn (case reported herewith).

Group 2.—Movement of the upper eyelid when the jaw is opened, but not by lateral movements: Ptosis. *(24) Helferich. *(25) Helfreich. *(26) Bull. *(27, 28, 29) Kraus. *(30) Bull. *(31) Vossius. *(32) Hubbell. *(33) Bernhardt. *(34) Bocci. *(35) Sinclair. *(36) Spicer. (37) Lebrun; young woman, ptosis left. (38) Higier; man, aged thirty-two, ptosis, right; on eating, right opened and left closed. On the right side, no face or eye muscles otherwise affected, but the whole mimic musculature of left side is. While the right ptosis is since childhood, left paresis has developed in

Fig. 3. Eyelid raised with mouth open.

the last nine months. By protrusion of the chin, eyelid (right) is raised. When turning left eye down or attempting to close it the right eyelid is raised. (39) Beaumont; child, aged two and one-half, epicanthus and double ptosis. Apparently cured by plastic operation for ptosis. (40) Bernhardt; patient, aged nineteen, ptosis right.

Group 3.—Eyelid raised with lateral movement of the jaw, but not with the simple opening of the mouth: Ptosis. *(41) Gunn. *(42) Schapringer. (43) Müller-Kannberg; girl, aged twelve, ptosis left. Left pupil smaller. (44) Hirschberg; child, one year old.

Group 4.—Movements of the lid with movements of the jaw, but no ptosis. *(45) Fuchs. *(46, 47) Fraenkel. *(48) Eales. (49) Aldor; boy, aged twelve, right lid moved when jaw moved to one side and on chewing and during speaking; paresis of superior rectus. (50) Adamuk; woman, aged forty. On eating, eyelid and eyeball were drawn up. (51) Just; girl, aged thirteen. Left eye; both by loud speaking and on opening jaw and by lateral movements. (52) Elschnig; man. When swallowing or chewing; greater when looking down than when looking up. (53) Friedenwald; girl, aged nine. Right lid drawn up when jaw is moved to same side as affected lid. (54) Friedenwald; woman, aged twenty. Slight droop of right eyelid; only began six years ago: during lateral movements of the jaw; crossed diplopia in left field with vertical displacement; image of right eye higher.

A further group may be formed to include such cases as were reported by Meyer. A father and daughter had ptosis of the upper lid, which raised consensually with the act of swallowing but not by mastication.

An analysis of the above list shows that this affection is found about equally in both sexes. Of 25 cases reviewed by Sinclair the affection was 18 times on the left side and 7 on the right, while in the cases which I have collected the affection is about equally divided between the two sides. Ptosis was present in 27 out of 32 cases in Sinclair's list, and of these 27 cases 10 had paresis of the superior rectus.

In the 22 cases added to this list, 19 had ptosis while 4 had weakness of the superior rectus. In several cases there is apparent weakness of the inferior oblique, though it is not definitely pointed out by the writers. The internal rectus was affected in 2 cases. The pupil was affected in 5 cases. Asymmetry of the face is noted twice.

Some Peculiarities of the Cases.—In Goldzieher's case there was apparently involvement of all the external ocular muscles supplied by the third nerve.

"Almost complete ophthalmoplegia from birth" is the description of Vossius' case. The ptosis was double, but only one side could be raised. His brother also had double ptosis and external ophthalmoplegia but could not raise his lids.

Beaumont's case had double ptosis.

In the cases, mentioned by Bull, von Reuss, and Higier, when the sound eye was closed the affected eye was opened as well as by opening the mouth. In Higier's case with right ptosis, the right lid raises and the left drops when chewing.

The movement of the eyelid was caused by projecting the jaw in the cases of Hilleman and Higier.

The movements of the eyelid could be checked by the action of the orbicularis in the cases of Bull, Hubbell, and Coburn.

Bull's patient could open the eye when the head was thrown back and when the other eye was closed.

Elschnig's case had greater elevation of the lid when the eye was directed downward, and one of Fraenkel's cases had no ptosis and the movement was only perceptible when the eye was looking down. Another of Fraenkel's cases had no ptosis at first and it only developed after some time, the lid movement becoming less marked. In one of Friedenwald's cases the symptoms only developed during the preceding six years.

The paresis of the muscles of the opposite eye was only noticed nine months before examination in the case of Higier.

Kraus had two cases, in one of which the movements of the eyelid became less marked and in the other they ceased altogether in time. One of Bloch's cases, however, increased with age.

Uhthoff's cases had diplopia when looking to the opposite side, as did also Higier's and one of Friedenwald's. The author's case also showed diplopia under proper tests.

Adamuk's case had associated movement of the eyelid, eyeball, and jaw.

An apparent anomaly is one of Friedenwald's cases, in which the lid moved upward when the jaw is moved to the same side as the affected lid. The

only explanation of this is that either the external pterygoid muscle of the opposite side was connected with the motoroculi nerve of the same side or that certain of the muscles (temporal, masseter, or internal pterygoid) of the same side which close the mouth were affected.

Coppez did a successful operation for the ptosis by the method of Gillet de Grandmont.

Beaumont also relieved the ptosis by a plastic operation.

Lacqueur suggested Panas' operation.

Etiology.—When Gunn's case was first reported a committee was appointed to consider the cause of this phenomenon, and they decided that an unusual relation existed between the levator portion of the nucleus of the third nerve and the pterygoid portion of the nucleus of the fifth nerve. Rosenmeyer, Nieden, Ole Bull, and others believe that it is a reflex condition. Sinclair opposes this view because it is one-sided, that cases occur with no ptosis and that it occurs also with lateral movements. Coppez speaks of an irradiation of nervous impulse communicated from one nucleus to the other. Because of the peculiarities observed in some cases, Helfreich has suggested that in such there is abnormal communication between the third and the seventh nerves. Hubbell, Helfreich, and others share the opinion that the oculomotor nucleus is imperfectly developed.

Near the aqueduct of Sylvius the descending root of the fifth nerve passes close to the nucleus of the third nerve, and any communication or abnormal commingling of the fibers could easily occur at this point. The writer shares the opinion with others that there is an abnormal relationship and association between the third and the fifth nerves, but the actual condition will never be known until a thorough post-mortem examination can be made of the brain of some person afflicted with this condition.

The similarity of this affection to chronic nuclear palsy or chronic poliencephalitis superior must not be forgotten—while simple misplacement of the nerve fibers may explain this condition, its relationship to chronic nuclear palsy is suggested by the following facts: (1) This condition is not always congenital—cases have been reported in which it appeared somewhat late in life. (2) This disease is not always stationary—in some it has increased, in others diminished. (3) while usually unilateral, it is sometimes double, especially the ptosis. (4) The lack of development of the face in some cases points to trophic disturbances in the seventh nerve—a condition often accompanying the infantile form of nuclear palsy.

This condition of nervous or muscular association seems to indicate that each ocular muscle in the group governing mastication has its individual nucleus in the base of the brain. A review of these cases suggests the intimate relation of these third nerve nuclei in the following order: Levator palpebræ, rectus superior, sphincter iridis, inferior oblique and rectus inferior. The masseter portion of the nerve fibers of the fifth nerve which supply the masticating group of muscles seems to be more closely related to the third nerve than do the other fibers of that group.

Treatment.—There seems to be very little that can be done to relieve this condition. Operations for ptosis have been successfully performed on these cases, and there seems to be no objection to them so long as the operation is not so radical as to cause permanent exposure of the eyeball

ACUTE CHOLECYSTITIS SIMULATING APPENDICITIS—TWO ILLUSTRATIVE CASES.

By ARTHUR L. CHUTE, M.D.,
BOSTON, MASS.

The striking similarity which acute cholecystitis may bear to acute appendicitis has been frequently observed and reported. This similarity seems to occur in two well-defined groups of cases, in which the anatomical conditions differ and in which the difficulty in diagnosis arises from different causes.

The greater number of instances comes in that group of cases in which the inflamed gall-bladder is in its normal position, but in which pain and tenderness, in the presence of distention and rigidity, are referred to the appendix region. The second group of cases is made up of those in which an inflamed gall-bladder reaches into the iliac fossa, either through great enlargement or through displacement. Here the error in diagnosis is the result of finding a painful, tender mass in the region of the appendix. This type is less common than the first.

Both cases which I report belong to the first type. Case I occurred in the practice of Dr. J. W. Elliot, and has been previously referred to by me (*Boston Medical and Surgical Journal*, 1899, Vol. CXL, p. 230). The patient was a woman of fifty-eight, with the history of an illness some months before, similar to the one for which she was operated upon. This illness was considered as appendicitis at the time. When seen she had been suffering for four days from an attack which had resembled appendicitis, in that the pain and tenderness had been referred to the right iliac region. She had vomited, but this had not been a very prominent symptom. She had had several chills, mild, with the exception of one the night before she was seen, after which her temperature rose to 106.2°, her pulse to 110°. In the intervals between these chills her temperature had been moderate, but with a pulse-rate which had impressed her physician as being disproportionately slow.

Examination showed her abdomen distended and generally tender. Although nothing could be definitely felt through the rigid muscles of the

right side of the abdomen, the point of greatest tenderness seemed over the appendix region. An incision showed that the appendix was not the seat of the trouble. The gall-bladder was found tensely distended, dusky, and with one or two beginning gangrenous spots on its fundus. There were only very slight omental adhesions, to protect the abdominal cavity from the rupture which seemed imminent. The gall-bladder contained several ounces of purulent fluid and two large stones, one of which was dislodged from its neck. Because of its necrotic appearance a portion of the gall-bladder was resected and the remainder attached to the lower layers of the abdominal incision. The convalescence was uneventful. This patient had never been jaundiced.

Case II.—A man of sixty, seen in October, 1902. For a good many years digestive distress with occasional attacks of pain referred to the epigastrium. At no time jaundice. Five days before he was seen he was taken with a sudden attack of abdominal pain, which was attended with vomiting. The pain was acute and at first rather diffuse; later it was referred more to the appendix region, and there was marked tenderness at this point. In the few days which intervened between the beginning of the attack and the operation the patient vomited from time to time; he also had mild chills. For the three days previous to operation he ran a temperature varying from 101°-104°, with the pulse ranging from 80 to 90. In the twenty-four hours just previous to operation, his general condition became much worse, though his pulse did not go above 90.

When seen, his abdomen was distended and tympanitic. Muscular spasm prevented any deep palpation. As soon as he was etherized his gall-bladder region was palpated and a large mass found there, while nothing abnormal could be felt in the appendix region. Operation showed a much distended gall-bladder with a spot which was almost necrotic on its fundus. There was neither exudate nor adhesions. The gall-bladder contained several ounces of purulent fluid and seventy-five small stones. It was attached to the lower layers of the abdominal incision and drained. During his convalescence, which was uneventful, several stones were washed out of the gall-bladder.

The misleading factors in both these patients were the referring of pain and tenderness to the region of the appendix, combined with so much distention and muscular spasm, as to make satisfactory palpation impossible.

The recollection of the combination of marked distention and a disproportionately slow pulse in the first case, led in the second instance to careful palpation under ether, and the recognition of the distended gall-bladder.

The greater number of cases, in which acute cholecystitis is mistaken for appendicitis, and the most important ones to recognize are of this type. As in patients of this degree of illness most surgeons are not likely to advise non-operative treatment, the particular importance of accurate diagnosis lies in the fact that it allows one to make his incision at the proper place. The low incision over the appendix does not permit one to deal with the gall-bladder without greatly increasing its length. The increasing use of the Ochsner treatment of acute appendicitis makes accurate diagnosis of great importance. It has happened that a slightly diseased appendix has been removed, and a fatally diseased gall-bladder left.

A consideration of the pain, tenderness, and distention, as shown by some of these cases of acute cholecystitis, is of interest. In some cases the pain has been, in the beginning, in the right hypochondrium, and then has been referred to the appendix region, as in a case reported by La Fort. More often the pain at the onset has been general, as in the two cases which I have reported, or it has been referred to the general region of the umbilicus. Later its greatest intensity has been referred to the region of the appendix, instead of to the right hypochondrium, there being at no time any suggestion of the real lesion so far as the location of the pain was concerned. Regarding the location of the pain in the iliac fossa, Adenot cites Potain as having pointed out the frequency with which patients with acute cholecystitis have pain radiating down the ascending colon into the cæcal region. Potain thinks this occurs rather more often in elderly people, in whom appendicitis is, relatively speaking, rare. It appears from my cases, and similar reported instances, that it is not necessary that the gall-bladder be adherent to the colon to cause this type of pain.

As to the tenderness, it is probable that if palpated early the greatest tenderness will always be found in the gall-bladder region. In the two reported cases, which were seen after several days illness, tenderness was found over the appendix, but I think it probable that the tenderness was at least no greater at this point than at other points in the right side of the abdomen, and that careful palpation, unbiased by the history of localized pain, would have shown that the appendix region, although tender, was not the point of maximum tenderness. Merk reports a case of acute cholecystitis in which he found great tenderness in both the right hypochondrium and at McBurney's point. Kennedy describes a case in which general abdominal pain finally became localized in the right iliac fossa, and in which rectal examination showed tenderness there. Under ether a distended gall-bladder, in its normal position, was made out; operation proved this to have been the cause of the iliac pain and tenderness. It is easily understood why cases such as Hotchkiss and Adenot have reported should present a tenderness in the cæcal region greater than that over the rest of the right side of the abdomen. In these cases pus from a gangrenous gall-bladder had trickled down along the colon and set up a peritonitis in the appendix region. These instances of perforation, however, do not properly belong in the cases under consideration. In most cases of this type I believe it is doubtful if the tenderness is really greater over the appendix than at other points in the right side of the abdomen, that its combination with localized pain, influences one's findings.

Due to the proximity of the gall-bladder to the transverse colon, cholecystitis is often attended with very marked abdominal distention. Czerny has recently called attention to two marked examples of this. Richardson, Körte, and others have cited instances in which, because of this marked distention, intestinal obstruction has been suspected. This very marked distention is in many cases the result of adhesions uniting the gall-bladder to the colon; sometimes as Riedel has reported, the colon is rotated by these adhesions, even through 180 degrees. In a certain number of instances this distention seems to be not so much mechanical as reflex, due sometimes to an exudate about the gall-bladder, not infrequently simply to the presence of a tensely stretched, inflamed gall-bladder. This latter was the condition in the two cases I have reported. This distention is enough

in itself to make palpation difficult; when attended with much spasm or rigidity, it may make the palpation of even a considerable mass impossible before the patient is etherized. It will thus be seen that in some cases it is impossible, before ether, to decide between acute cholecystitis and appendicitis. The pain, tenderness, and spasm of the abdominal muscles is such as would apply to either. The distinguishing feature, the presence of a mass in the gall-bladder region, or the absence of one in the appendix region, cannot be determined because of the distention and rigidity of the abdominal muscles. Kehr has called attention to the impossibility of making a diagnosis in some of these cases before the patient is etherized. Körte, Gibbon, Kennedy, and others give cases illustrative of this. Under ether there should be little difficulty in arriving at the correct diagnosis in nearly all cases of this sort. This may not be possible, however, if one has to do with a shrunken gall-bladder which is inflamed.

Adenot says that any case of supposed appendicitis, that is not perfectly typical, should make one consider carefully the possibility of an inflamed gall-bladder. While the finding of a distended gall-bladder is the only point on which one can definitely base a diagnosis in doubtful cases, yet there are several things which should lead one to consider cholecystitis especially carefully. Two symptoms, by no means constantly seen in acute cholecystitis, have, I feel, when present, a good deal of suggestive value. One is the presence of marked distention, which is common, and to which reference has already been made. The other is the occurrence of a pulse-rate which is disproportionately slow when compared with the temperature. This last is well shown in Case II, in which instance it led me first to suspect a cholecystitis. Richardson has spoken of the pulse in acute cholecystitis as rarely being above 100, and he has reported a case presenting symptoms of appendicitis in which the pulse varied from 70 to 100 for five days, while the temperature was about 103°. This disproportion between the pulse and temperature is not present in any considerable proportion of cases, but when it is, I believe it is of a good deal of suggestive value, especially if it has existed some days.

There are some other things which are also of value in the consideration of these cases. Deaver has found that the vomiting is more marked and persistent in cholecystitis. The age of the patient is of some aid, extreme youth decreasing the probability of cholecystitis, while middle or advanced age increases it. It must, however, be borne in mind that either disease may occur at any time of life. A previous attack of jaundice may be of suggestive value; the absence of a history of jaundice, on the other hand, means nothing, as jaundice is relatively rare in cholecystitis, being absent in from 80 per cent. (Kehr) to 90 per cent. (Riedel) of the cases.

There are some cases, with the gall-bladder in its normal position, in which cholecystitis simulates appendicitis so perfectly that the point on which the diagnosis has to depend is the discovery after etherization of an enlarged gall-bladder, which up to that time could not be made out. In a few instances when the gall-bladder is shrunken, the absence of a mass in the iliac region may be the point on which the diagnosis must rest, if indeed it can be made.

The second type of case is that in which one has to do with an inflamed gall-bladder, which, either through great enlargement or through great displacement, reaches into the iliac fossa. It is less common than the first. In these patients the diagnosis between acute cholecystitis and appendicitis is difficult, in many cases impossible before the abdomen is opened. The disadvantage of incorrect diagnosis is less than in the first type, as an incision in the appendix region is adapted to the treatment of the trouble. This condition, in which the gall-bladder reaches into the iliac fossa, may come about through a sinking of the liver and gall-bladder, usually as part of a general enteroptosis, or may be due to the elongation of an atonic gall-bladder. The cases which are the result of an enteroptosis are said to have a peculiar liability to trouble, as accompanying the displacement of the gall-bladder downward, there is said to be a rotation on its vertical axis. The gall-bladder in this type of case may be free or it may be adherent in the iliac fossa. When a gall-bladder of this sort becomes inflamed, there is not only pain in the right iliac fossa, but also a mass which is tender and which is protected to a greater or less degree, by rigid abdominal muscles, making its similarity to appendicitis very real. Adenot, in his paper, has collected a number of cases of this sort. Kehr, Morestin, and Mouchet and Hallopeau report cases belonging to this type.

A correct diagnosis is possible in some of these instances, especially when the gall-bladder is not adherent. If the condition is due to ptosis, the sinking of the lower edge of the liver may give a suggestion. Adenot thinks the lateral mobility of the displaced gall-bladder in those cases in which it is not held by adhesions, should lead to a recognition of the nature of the mass. He also says the nearness of the mass to the surface is a valuable help in distinguishing between an inflamed and displaced gall-bladder and the mass about an inflamed appendix. In cases in which the enlarged or dislocated gall-bladder is adherent in the iliac fossa the correct diagnosis will rarely be made.

Of interest in connection with this subject, and adding still further to the confusion which exists between cholecystitis and appendicitis, are the cases in which both cholecystitis and appendicitis occur at the same time, and those in which an inflamed appendix, or an appendix abscess, is found in the region of the liver or gall-bladder. La Place and Merk have reported cases in which both the gall-bladder and the appendix have been in a state of active suppuration at the same time. Ochsner has commented on the frequency with which he has found both organs simultaneously diseased. Kehr speaks of the cases in which he has found a diseased appendix accompanying gall-bladder trouble. Becker collected, mostly from the German literature, the cases reported up to 1902 in which both cholecystitis and appendicitis had been found together; to these he added five personal instances. When a chronic recurring appendicitis accompanies cholecystitis it may bring about confusion in the diagnosis in two ways, by the history of typical and recurring attacks of appendicitis or by the presence of a mass of tender adhesions in the iliac fossa.

Analogous to the cases in which the gall-bladder is found in the iliac fossa, are those in which an inflamed appendix, or an appendix abscess, is found in the region of the liver. These conditions are the result of a rudimentary ascending colon, or of an unusual length and upward direction of an appendix. Typical instances of this have been reported by Curschmann and Naunyn. Disease of a normally placed appendix is, however, rarely mistaken for cholecystitis.

A review of the literature of this subject shows that there is not infrequently a great similarity between the picture of acute cholecystitis and that of acute appendicitis. It is much more common for acute cholecystitis to be mistaken for appendicitis than the reverse. The correct diagnosis can usually be made by careful palpation after the patient is etherized. In a few cases a correct diagnosis cannot be made before the abdomen is opened; this occurs most often in the cases in which there is an appendix abscess in the region of the liver, or an inflamed adherent gall-bladder in the appendix region. An additional complication in the diagnosis of these cases is the fact that both cholecystitis and appendicitis, may occasionally occur at the same time. Cases have been reported in which both diseases were in an acute stage; this is very unusual. The combination of an acute cholecystitis with a chronic appendicitis is not very uncommon; the reversed condition of affairs has been reported less frequently; both are especially misleading through the history.

In dealing with supposed cases of either of those two most common intraabdominal inflammations, one should always bear in mind the closeness with which they may simulate each other. When at operation the state of the organ investigated does not satisfactorily account for the patient's condition the other organ should always be examined. The lack of this precaution has, in at least one recorded case, led to the removal of a slightly diseased appendix, while, as the autopsy showed, the symptoms had been caused by a gangrenous gall-bladder which had not been discovered.

THE TREATMENT OF SYPHILIS BY HYPODERMIC INJECTION OF MERCURY.

A PRELIMINARY REPORT.

By LAWRENCE T. ROYSTER, M.D.,
NORFOLK, VA.

The treatment of syphilis has varied so little in its essential features during the past century that I shall not attempt to discuss the changes that have taken place, but will give merely an outline of my own management of this very interesting disease. No man should ever attempt to diagnose syphilis from the initial lesion alone, for although we may feel reasonably assured that we have a chancre to deal with, yet there is no absolute certainty, and the physician who commences treatment before the appearance of the eruption, does himself great injustice and his patient irreparable wrong.

The management of syphilis resolves itself into two stages (1) before and (2) after the appearance of the eruption.

I shall not discuss the management of the late manifestations, as I am dealing more particularly with the acute stage.

1. Before the appearance of the eruption: When a patient comes to me with a probable chancre, only mildly antiseptic treatment, such as boric acid wash, is used. This is all I do for the sore so long as there is ground for the belief in the syphilitic nature of the lesion. During this period of waiting, however, I instruct the patient in cleanliness and the care of himself.

After carefully explaining to him the exact nature of the disease he has probably contracted, and what a menace he is to the health of those around him, not in such terms as to make him feel that he is a leper, yet strong enough to impress him with the importance of care, I send him to a dentist to have his teeth thoroughly overhauled. Tartar must be removed, cavities filled, and snags drawn. I then have the dentist run his scarifier up between the gum and the teeth and get at whatever tartar may be concealed there.

This is imperative because a foul and dirty mouth is in constant danger of salivation. The mouth had better be attended to early, because it will then have time to recover from the soreness caused by scarification before the commencement of mercury administration; and also during the early stage the dentist is in less danger of infection. A good mouth wash, slightly astringent, is advisable, as long as he is under treatment.

Mercury has two very important incompatibles, viz., whiskey and tobacco, and the more of either of these a man is taking, the less mercury can he take; so I take advantage of the primary stage to cut off these two articles completely and entirely. If the patient is run down or recovering from illness of another kind, I usually administer some form of tonic treatment which is with benefit kept up well into the eruptive stage.

2. After the appearance of eruption. During the initial stage I have the patient report to me as often as possible—every day, or at least every second day—at which visits I examine him from head to foot for eruption and glandular enlargement. On the appearance of the eruption and my satisfaction of

its specific nature, I institute anti-syphilitic treatment. Briefly this consists in the exhibition of (1) mercury in one form or another, and (2) iodides, either alone or with mercury.

I will leave the iodides out of consideration and confine myself to the important portion of our discussion, viz., What is the best form and manner of administering the all-important remedy—mercury? Mercury is administered to syphilitic patients in two general ways; by the mouth and by the skin. I never give mercury by the mouth if it is possible to give it in any other way. The objections to this mode of administration are these:

Mercury in any form by mouth is almost necessarily going to upset some portion of the alimentary canal. In case of the bowels when there is griping or diarrhœa, or both, it shows a non-absorption of the drug. We are told that we must overcome this griping by the administration of opium. Now there is a great question in my mind that such procedure is logical. Does opium promote absorption or merely stop the griping? And if the latter be true we gain nothing, but on the contrary are groping absolutely in the dark, and the patient is not getting sufficient dosage, and is therefore losing valuable time. Another objection is that it is such an easy thing for the patient to forget to take his medicine and after a short time to neglect it altogether, and then his symptoms recur. Mercury by mouth also acts very slowly. So as between the mouth and skin, the mouth is hardly worthy of second consideration.

Mercury is administered by the skin in two ways—by inunction and by hypodermic injection.

The method of mercurilization by inunction is time-honored and tried, and is endorsed by many of the world's most eminent syphilographers, and is worthy of all the confidence which has been placed in it. It is effective, quick in action, and sure. It does not cause digestive disturbances and does not require the same frequency and amount of attention from the patient as does the mouth method, but it has the disadvantage of being very troublesome, and being easily neglected, and to most people it is a rather disagreeable method of treatment. But when it can be administered by an expert rubber, such as at institutions and resorts devoted to its use, it is an excellent form of treatment. It is especially useful in congenital cases, though I see in the more recent foreign literature that the needle is being used with good effect in these cases also.

The other way of administering mercury by the skin is by hypodermic injection. This method was introduced many years ago by Lewin in Germany, but although used by him for some time, and with some success, he finally abandoned the method as too irritating. From that time on other investigators have used this method with varying degrees of satisfaction. So far as I am able to find, the majority of these men used salts of mercury which were either slightly soluble or totally insoluble. Using the former in aqueous solution and the latter suspended in oil. Recently in this country there has been used a soluble salt of mercury in oil. I have tried all of these methods and after something over one thousand injections, I am now confining myself to an aqueous solution of the bichloride.

The great advantages of this method are that as a rule it does not cause any digestive disturbances; the patient gets rapidly under its influence; the trouble to both patient and doctor is a minimum; the exact amount of the drug that the patient is receiving is known at all times, and what is above all other considerations the physician administers the injection himself, thus largely preventing the usual neglect in taking the mercury, and also keeping the patient under his eye constantly during the active stage of the disease. During the late stage of the disease the great infrequency of the treatment necessary is a great help. The only possible objections to the mode of treatment are the irritation that it causes some patients and the induration at the seat of injection. As will be seen later, I think both of these objections have been largely overcome.

The necessary articles are a graduated glass hypodermic syringe, platinum needle three-quarters to one inch long exclusive of the shank, and an aqueous solution of bichloride of mercury. I have the solution made up with an equal amount of common salt, as I thus secure a better solution and quicker absorption.

As to the mode of administration, I do not think it necessary to exercise any more care in this than in giving an ordinary hypodermic injection. The mercury is antiseptic and I have never had an abscess.

The technique of injection is important. It is best to inject into a fleshy portion of the body. Some use the muscles of the back, others the thigh, and still others the buttocks. I prefer the last. I sit and have the patient stand in front of me with bared buttocks; he is then instructed to tighten them (by contracting the gluteus); the needle is then stuck quickly straight in; he is told to loosen the buttocks and the injection is made quite slowly, taking fully a minute to complete the operation. I then withdraw the needle quickly, and placing a wad of absorbent cotton on the sight of injection, rub with this in a sort of rotary massage for another minute, and the injection is complete. The injections are made into each buttock alternately.

The dose employed in this method is the most important feature of the subject. When I first employed these injections I adopted the exact routine used by other observers, viz., commence with 10 minims of one-per-cent solution, and increase one minim each day up to 30 minims, then change to 15 minims of two-per-cent solution every other day, increasing to 30 minims; keep at this amount and gradually increase the time between the injections until by the end of one year the injections are made only once a week.

I found this method eminently satisfactory with the exception of two features; some patients suffered considerable smarting at the seat of injection for an hour or more, and the induration was disagreeably large. I observed that both of these phenomena were more marked as I gave the larger number of minims, and were less with 15 minims of a two-per-cent solution than with 30 minims of a one-per-cent. solution, although the same amount of mercury was injected, so I concluded that both the pain and induration were probably due to the quantity of fluid rather than the amount of mercury injected. I began to use a more concentrated solution of the mercury, employing a four-per-cent solution, and varying my routine as follows: Commence with 5 minims of a two-per-cent solution and increase up to 10 or 12 minims, and then change to 5 minims of a four-per-cent solution and increase up to about 10 minims and make this the maximum dose. The use of this concentrated solution has reduced both pain and induration to a minimum, and to my mind leaves this the most satisfactory method of treatment.

If a patient comes to me with the eruption well out, I still use an injection every day until the eruption has disappeared; but when the eruption is slight or seen very early, every other day usually suffices. The intervals are gradually lengthened

until, by the end of about ten months, I am administering only one injection each week, and this is maintained until the end of two and one-half or three years. Of course it must be remembered that every case is a law unto itself and needs different handling according to circumstances, but this, in brief, is the outline of hypodermic treatment of syphilis.

A NEW PATHOGENIC THROAT ORGANISM.

By B. H. STONE, A.B., M.D.,
BURLINGTON, VT.
BACTERIOLOGIST, VERMONT STATE BOARD OF HEALTH; INSTRUCTOR IN BACTERIOLOGY, UNIVERSITY OF VERMONT.

THE winter of 1903-04 has been characterized by a more or less general appearance throughout this State (Vermont) of cases of an acute inflammatory condition of the throat, accompanied by a severe but not fatal toxæmia lasting from twenty-four to forty-eight hours and then subsiding. The cases are usually ushered in with chilliness, pain in head and limbs, and a coryza, often accompanied with an unusual amount of sneezing. In nearly all of these cases, the tonsils have been more or less swollen, the soft palate and uvula œdematous, and in many there has been a distinct false membrane, white in color and very tenacious.

Of eighty-one of these cases which have been studied bacteriologically, forty-four have shown a membrane, but this percentage is probably too high, for the reason that the throats of most of these cases were cultured for suspected diphtheria. Of the cases which have been under personal observations the percentage of membranes have been much lower. The toxic symptoms subsiding in two days leave, in most cases, an irritable condition of the mucous membrane, which persists for some time, and in some instances the acute symptoms have been followed by great weakness. The attacks are not, as far as can be noticed at present, confined to any particular age, affecting both old and young.

These cases have been variously diagnosed diphtheria, grippe, and simple cold, accordingly as the symptoms have been of varying severity, and the cases with or without false membrane production.

That they are not cases of true grippe is proven by the fact that the period of toxæmia is much shorter and that in none of them is there found the presence of Pfeiffer's bacillus.

That they are not cases of diphtheria is clear from the entire absence of any organism resembling the true diphtheria bacillus in the false membrane.

The remarkable fact about these cases has been the severe toxæmia coming on suddenly and lasting only a short time, and the universal appearance in the throat of a peculiar diplococcus.

The organism was first noticed by the writer during the winter previous to this one in the routine examination of cultures from suspected diphtheritic throats. It first gave rise to some confusion, owing to its resemblance to certain very short granular forms of the diphtheria bacillus. When first noted it was confined to the cultures received from a certain locality.

The following case histories, for which I am indebted to Dr. C. H. Beecher, are fairly characteristic:

CASE I.—Student: when first seen complained of feeling chilly, slight pain in limbs, back, and head, and some nasal discharge and considerable soreness of the throat. He had felt chilly for the past twenty-four hours, but had had no definite chill. The pain in limbs, back, and head had appeared in the last few hours, as had the nasal discharge, which was accompanied by excessive sneezing. The throat had felt dry and gave some pain on swallowing. Temperature 102 and pulse 110. On examination the mucous membrane in throat, especially over the pillars of the fauces, tonsils, and uvula, was of dusky red, considerably darker than the surrounding membrane, and appeared œdematous or gelatinous. This condition was especially noticeable on the uvula. The inflammatory area was coated with a tenacious whitish mucus. Cultures made at this time showed the presence of a peculiar diplococcus in almost pure culture. The temperature, chilliness, and the pain only lasted two or three days, gradually disappearing, but the soreness of the throat and the depression, which was considerable, lasted about a week. Repeated cultures of the throat showed the same organism as above.

CASE II.—Miss C.: Came into the office complaining only of feeling "mean" (weakness and muscular pain) and of a sore throat. On examination, the throat was congested and œdematous. There were six or eight whitish patches of adherent exudate on the tonsils and pharynx. Bacteriological examination of the throat secretions showed the same diplococcus as was found in Case I. Temperature at this time was 103, pulse 120. The next night the patient slept poorly, and the following day the throat was more painful and more œdematous, but the patches of exudate were practically the same size as on the previous examination. Temperature and pulse as on the preceding day. The throat was again cultured with the same results as before. After the second day the symptoms gradually improved. The patches disappeared and the patient felt well enough to resume work on the fifth day from the first examination. Cultures taken then still showed the pure culture of the diplococcus.

In addition to many cases of this sort, which are apparently the typical manifestations of the pathogenic effect of the diplococcus mentioned, the same organism has been met with in several cases of typical follicular tonsillitis, and in the throats of three cases of scarlet fever and in many cases of irritable throats following diphtheria. In one case of purulent meningitis, following middle-ear disease, the diplococcus was found in the meningeal pus.

The organism occurs in the secretions and exudations of the inflamed mucous membrane. It is diplococcus with its adjacent sides slightly flattened. When stained by Loeffler's stain, one or both of nearly every pair has a distinct metachromatic granule which stains very intensely. When stained with fuchsin the granule does not show. One of the pair is often smaller than the other. In preparations made from bouillon or blood serum cultures, the pairs are clumped in irregular bunches, apparently held together by some gelatinous material which does not stain. They vary from one-half to one micron in diameter, and the flattening on adjacent sides is sufficient, so that the combined diameter of the pair is but little greater than the opposite diameter of the single member.

They stain readily by Loeffler's and fuchsin, and by Gram's method, although the clear space between the members of the pair and the polar granules are best seen with the first stain. They possess no flagella, spores, or demonstrable capsule. Almost no growth occurs in gelatin and there is no liquefaction.

On an agar plate grown at 37° C. for twenty-four hours round regular colonies appear. They are white raised (pulvinate), and very tenacious, so that it is impossible to take up any of the colony without taking it all. They grow very little larger than the head of a shawl pin.

On agar streak cultures the character of the

growth is similar to that on plates. The white colonies are first discrete, regular in outline and pulvinate, but gradually they coalesce along the line of the needle tract, and the result is a more or less continuous nodular growth. Growth is never luxuriant, however, and does not spread laterally far from the needle tract.

On blood serum growth is quite luxuriant, appearing first as moist, glistening, white colonies, which soon coalesce, forming a viscid, extremely tenacious skin over the whole surface of the medium. The medium is not liquefied.

On potato, growth is similar to that on serum, only less luxuriant. The potato is not discolored. In bouillon its growth forms a white stringy sediment, sticking tightly to the bottom of the tube. There may be a slight general turbidity. In litmus agar it produces no change in color. It produces nitrites in nitrate broth, does not form indol or gas or acid in glucose, lactose, or saccharose solution.

For all of these growths it requires oxygen and a temperature near 37°C. The thermal death point is between 60° and 70°.

Animal inoculations were made with the following results:

Animal No. I.—An intraperitoneal inoculation of a young guinea-pig proved fatal to the animal in five days. A seventy-two hour bouillon culture was used. The animal showed few symptoms of infection until the fifth day, when symptoms of profound toxæmia commenced and increased very rapidly, resulting in death in a few hours. An autopsy showed a slight subcutaneous œdema, with a collection of white, viscid, tenacious pus around the peritoneal wound. Peritoneal cavity containing much semi-solid tenacious exudate, which microscopically showed fibrin, pus cells, and diplococci. Mesenteric glands were all enlarged, and showed the presence of the same organism. Blood serum cultures made from the peritoneal exudate resulted in a growth of a pure culture of this diplococcus.

Animal No. II.—Rabbit. Inoculated intravenously with an old bouillon culture. This animal died in convulsions within twelve hours of inoculation. An autopsy showed a general congestion of the viscera, especially noticeable in the kidneys and liver. The bladder was filled with dark colored, apparently bloody, fluid. Smears of liver and splenic pulp were negative. Five cultures taken from heart's blood all showed pure growth of the diplococcus.

Animal No. III.—Guinea-pig inoculated with the filtrate after passing an old seven-day bouillon culture through a Berkfield filter. This animal on the second day showed an irregular pulse, and on the next day was unable to walk, staggering and finally falling over. Spasms developed, and the animal finally died in forty-eight hours from the time of inoculation, presumably as a result of the soluble poison produced by the organism in its growth in the bouillon.

Animal No. IV.—Guinea-pig inoculated subcutaneously with a young bouillon culture failed to respond.

Animal No. V.—A guinea-pig was inoculated by slightly abrading the mucous membrane of its lips and rubbing in a young culture. This experiment was negative.

Other animal experiments have been confirmatory of the results obtained from the above described inoculations, showing that the organism is variably pathogenic for laboratory animals.

The fact that the poison produced by this diplococcus in its growth is soluble, and that an attempt to isolate ptomains by Breiger's method was negative, renders it fairly certain that the poison is a true toxin.

The writer is thoroughly convinced that this organism stands as the etiological factor in the above described throat cases, even though efforts to reproduce its peculiar lesions on the mucous membrane of laboratory animals have been so far unsuccessful.

1. Because it has been found constantly present in these cases in almost pure cultures and isolated while no other organisms are constantly found.

2. Because it is not generally found in healthy throats. An examination of over two hundred cultures, made from healthy throats, have failed to show this diplococcus in hardly any case in which it could not be explained as persisting after an acute attack.

3. Because it is toxic for laboratory animals producing on serous membrane an exudate analogous to that produced in the throat, from which exudate it has been recovered in pure culture.

4. Because it produces a soluble toxin sufficiently virulent to kill animals.

5. Because its blood serum growth has a peculiar viscid character, suggesting the extreme viscidity of its exudate in the throat.

On Black Urine.—Archibald E. Garrod gives a brief account of the importance which has been attached to this phenomenon from ancient times, citing cases in which the condition existed in healthy persons. He then gives a list of diseases which may produce black or dark urine. The first disease discussed is jaundice. It is not common for urines containing bile pigment to approach to blackness, but when there is a large amount of biliverdin, together with bilirubin and other varieties of bile pigment, they may appear black. Black urines of this kind are more common in cases of long-standing jaundice in which the skin has become a dirty greenish hue. The writer thinks that it is probable that many of the black urines described in the earlier literature owed their blackness to the admixture of blood or of hæmoglobin. The term "black water fever," the writer states, bears witness to the character of the urine which may result from the presence of hæmoglobin. In cases of poisoning by certain drugs the urine may appear opaque and practically black. In hæmatoporphyrinuria the color of the urine usually resembles that of port wine, but various degrees of tint are met with. True melanuria associated with melanotic sarcoma is a rare condition. In melanuria the urine has usually a normal color when passed, although it may have a brown tint, but after being exposed to air it quickly becomes brown, and finally as black as ink. In alkaptonuria as in melanuria the urine is of normal color when fresh but darkens on standing. In the condition of ochronosis—a term given to a blackening of the cartilages and of some other tissues—the urine has been observed in a few cases to blacken on standing.

Any morbid process which leads to abundant excretion of indican may give rise to dark urine—intestinal obstruction from any cause, excessive bacterial activity in the intestine, or putrefactive changes in collections of pus. Indicanuria is not nearly so well recognized as it should be. It has been noted in some cases of phthisis that urine became black on long keeping. The writer mentions several instances of uncertain nature in which the urine has been discolored. He also gives a list of articles of diet and drugs which have the same effect. As to prognosis, it may be grave, as in the case of true melanuria; or as in alkaptonuria the condition may be harmless. Between these extremes of morbid conditions are various degrees of gravity.—*The Practitioner.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51, FIFTH AVENUE.

New York, August 13, 1904.

THE NERVOUS COMPLICATIONS OF INFLUENZA.

THE complications and sequelæ of influenza are so numerous that the literature on the subject is voluminous to a degree. Indeed there is probably no disease which has been more widely dealt with during the past twenty years by the medical scribe than influenza in all its manifestations and ramifications. Grippe has a peculiarly sinister influence upon the nervous system. It seems to have a special predilection for the nervous centers, and the person who gets over an attack without serious damage to or grave organic and functional disturbance of the nervous system may deem himself exceptionally fortunate. The health of many an individual has been completely wrecked by this insidious malady.

Dr. Charles Louis Mix, in *Medicine*, for May, 1904, discusses the nervous complications of influenza at considerable length. The nervous complications of the prodromal period are of great variety and of protean form, ranging from headaches and backaches to delirium, catalepsy, katatonia, hysteria, and many other psychoses, varying in intensity in proportion to the extent of the toxæmia

The nervous complications of the fastigium and period of lysis are both toxic and bacteriæmic, or degenerative and inflammatory. Inflammatory complications are encephalitis, both hemorrhagic and purulent, cerebrospinal meningitis, and myelitis. Toxic complications are various psychoses and meningitic-like forms, to which the term meningism is applicable.

The diagnosis of grippal meningitis is at times most difficult. Cases affecting chiefly the base may so resemble epidemic cerebrospinal meningitis as to be indistinguishable from it by symptomatology alone, since both begin suddenly with a chill followed by fever and cervical rigidity, and herpes is characteristic of both; although the latter symptom is possibly more prevalent in the epidemic form. Only the differentiation by lumbar puncture is absolutely reliable, though prevalence of epidemic influenza or of epidemic cerebrospinal meningitis may accurately indicate the correct diagnosis. There is also allied to true grippal meningitis the form named by the French pseudomeningitis or meningism, cases of which have been reported by Lépine and others, and the differential diagnosis between grippal meningitis and these cases is extremely difficult. Many of them begin in a foudroyant manner, the symptomatology of the case of Hagerstedt answering well as a typical example. Post mortem no true meningitis is found, and no organisms; there is nothing except possibly a hyperæmia of questionable nature, and possibly an increase of serum. The conclusion is that these cases are due to an intense toxæmia.

The nervous complications of influenza occurring during convalescence are entirely toxic. They therefore, in Dr. Mix's opinion, resemble closely in a way the nervous complications of diphtheria.

That influenza exerts a severe poisonous effect upon the nervous system was suspected and confirmed by Leichtenstern three years before Pfeiffer discovered the influenza bacillus. This nerve poison is capable of bringing on degenerative processes, especially in the peripheral nerves. If the toxins are not sufficiently virulent, or if the resistance of the organism invaded is sufficiently strong, functional rather than degenerative changes may result. In general, Dr. Mix states that the convalescent toxic effects of influenza may be subdivided as follows: (1) neuralgia, functional; (2) myalgia, functional; (3) multiple neuritis, organic; (4) focal neuritis, organic.

Referring to focal neuritis in connection with influenza and as a causative factor of deafness, not secondary to disease of the middle ear, Dr. Mix holds the view that just as the optic nerve is susceptible to the toxins of influenza, so also is the trunk of the auditory nerve, which in its anatomy closely resembles the optic nerve. The writer then goes on to declare his disbelief in the existence of the ninth nerve. He revises, according to his views, the generally accepted opinions on this matter as follows: "I am of the opinion, from anatomical and pathological reasons, that the glossopharyngeal, the pneumogastric, and the spinal accessory nerve form one nerve-complex, the sensory fibers being received into the sensory vagus and so-called glossopharyngeal nucleus situated at the anterior end of the vagus nucleus, and also into the accessory sensory nucleus, the nucleus of the fasciculus teres; the motor fibers coming wholly from the nucleus ambiguus and the nucleus of the spinal accessory. The supply of these three nerves in one is the upper portion of the alimentary canal and the viscera, the motor supply extending as low as the heart, the sensory supply still lower. The pharyngeal plexus receives all of its motor fibers from the spinal accessory and none from the glossopharyngeal, the latter containing no motor fibers, despite the statement to the contrary in Gray's Anatomy, to the effect that the stylopharyngeus muscle is supplied by the glossopharyngeal nerve." We wonder what Sir William Gowers would have to say to this statement.

The writer says, in reference to the para-grippal or meta-grippal diseases, that the onset of these is, as a rule, after the subsidence of the influenza, but not in every instance. Thus epilepsy may almost immediately follow influenza. Neurasthenia is undoubtedly the most prominent of the meta-grippal affections. This condition, it would seem, occurs when the toxins are less virulent or the organism more resistant. The leading feature of the neurasthenia is hypochondria and motor weakness. A third post-grippal disease is hysteria, all its symptoms manifesting themselves. In addition to the more common post-grippal conditions, other diseases

have been reported occasionally. Tabes dorsalis, paralysis agitans, spastic spinal paralysis, multiple sclerosis, Basedow's disease, and progressive paralysis of the insane have all followed influenza. In all of the above mentioned maladies influenza has only acted as the exciting cause. Again tetany has sometimes been observed after influenza, while chorea as a post-grippal disease has been repeatedly seen, cases having been reported by Rosenstein, Leyden, Van Deventer, Demme, Villard, Eichorst, and Leichtenstern.

The psychoses of influenza develop at any stage, even preceding it; according to Kraepelin the majority of cases occur during convalescense. Of all the epidemic diseases influenza is the one most frequently followed by psychoses. These, moreover, are not exhaustion-psychoses, but belong rather to the toxic group, being due to the special neurotoxin of influenza. Leichtenstern states that the psychoses often are found in those showing no hereditary or neuropathic involvement. Bossers and Althaus concur in this view. On the other hand, Kraepelin, Mispelbaum, and others hold that the psychoses of influenza develop upon an inherited or acquired neuropsychopathic tendency. Psychoses develop both during the prodromal stage and the febrile stage. A third group is made up of those coming on during the period of convalescence. The explanation of these psychoses is not to be found in the toxins themselves, but in the after-effects of the toxins upon cortical nutrition. The fourth group of cases is the post-grippal or meta-grippal psychoses, and fortunately these are very rare. In the meta-grippal cases the prognosis is not good; in general paralysis of the insane, of course, it is absolutely bad; and in the psychoses it is likely to be poor. It will depend upon the previous history of the patient, the family history, and the hereditary taints.

Influenza has an extraordinary aptitude for discovering the weak points in the armor of health. If an individual, through the sins or misfortunes of his fathers, inherits a predisposition to any disease, an attack of influenza will in most instances develop this disease. This statement is especially true of affections of the nervous system, and renders, in these times, influenza a malady to be greatly dreaded. Owing to the mode of life of modern civilized nations, nervous instability is frequent, and influenza brings out into active prominence latent flaws which otherwise might lie dormant. Considered from almost all points of view, influenza is perhaps the most deadly disease to which the modern individual is subject. When it does not kill, it either cripples or leaves the victim of its onslaughts a worse man physically and mentally than he was before the attack.

SPECIALLY PREPARED IMMUNE SERA.

One of the puzzling and sometimes discouraging facts connected with serum therapy is the uncertainty in the results, a brilliant success in one case being followed perhaps by absolute failure in a seemingly perfectly similar case. This is especially noticeable in pyæmic and septicæmic infections, in which the best results have been obtained by, or at least claimed for, immune sera. Yet it is also in these forms of infection that the greatest uncertainty in results is noted. One of the most active causes of failure in these cases is doubtless that the serum employed is not bactericidal in relation to the particular species of microbe causing the disease. In the case of the streptococcus, for example, a serum fatal to one species may have little or no repressive influence on another species. To obviate this objection to specific treatment, the attempt has been made to obtain a universally immune serum by employing a mixture of streptococcal forms. But until we know how many species of streptococci there are having each its specific pathogenic action, and can prepare a serum from all, the use of the multivalent sera is suggestive of the shotgun prescriptions of our fathers in medicine.

In a discussion of this point in *The Lancet*, of July 16, 1904, T. J. Horder says very truly that "the ideal serum for the treatment of any particular patient suffering from streptococcus infection must be one obtained by the use of the organism actually causing the disease in that patient, for this serum can alone be guaranteed to be specifically associated with the causal agent of the disease. To obtain this ideal serum we have but two alternatives open to us —either we must possess certain trustworthy tests whereby we can recognize the particular streptococcus obtained from the patient, so that we may choose a serum already at hand and produced by the use of that organism, or we must specially prepare the serum by the use of the very streptococcus which we have obtained in the course of our bacteriological diagnosis of the case." It is possible that the first of these alternatives may be available some day, but it will require a well-developed technique to diagnose promptly and with absolute certainty the species of streptococcus present in any case; but when our methods are so perfected that this can be done the next difficulty will be always to be armed with the specific serum for instant use. The second alternative is not so hopeless looking, but, as Dr. Horder observes, it is practicable only when the duration of the disease extends over at least eight weeks, since this interval would seem to be necessary before the serum of a horse inoculated with a streptococcus is likely to contain antibodies of sufficient strength to make it of therapeutic value.

Cases of general streptococcus infection of sufficiently long duration to promise any success from this method of treatment are not common, but they are sometimes encountered. Dr. Horder reports one of the kind—a case of ulcerative endocarditis of streptococcal origin lasting over six months. When the nature of the infection was discovered by means of a blood culture, all the various antistreptococcus sera on the market were tried one after the other, but without success. A specific immunized serum was then obtained from two animals by the use of the patient's particular streptococcus, and this serum was freely used for a period of over two months, during which time more than 550 c.c. was injected. The failure with this serum was as marked as had been that following the use of the commercial sera, and at no time did the temperature chart suggest that the treatment had influenced the course of the disease in the slightest degree.

The experiment was therefore altogether inconclusive in its results, but the case is nevertheless worthy of record and of comment. It was one of

the first of the kind, if not the first of any kind in which treatment was by a serum prepared from the patient's own microbes, and the failure might have been influenced by other factors, such as that of a mixed infection. The idea is worthy of further development before being abandoned as impracticable.

Military Medical Journalism in the Present Day.

At the annual meeting of the American Medical Editors' Association, held in Atlantic City, June 6, Major J. E. Pilcher read a paper on the above subject. According to the facts gathered by Dr. Pilcher, there are in existence to-day twenty-six military medical journals, which may be divided into three classes: (1) Official medico-military journals, published by the governments of the countries in which they are issued. (2) Private military medical journals, published by individuals or private firms and supported by subscriptions and advertisements as are other medical journals. (3) Periodical publications of associations of military medical officers. The first class contains nine publications —including those published by the governments of Belgium, France, Germany, Italy, Norway, and Spain.

Of the second class—journals published by private enterprise—there are three in Austria-Hungary and one each in Argentina, Finland, France, Germany, Holland, Roumania, Russia, and Spain. In the third class are numbered the journals published by the Danish Military Medical Society, the Japanese Association of Military Surgeons, the Swedish Association of Military Surgeons, the Central Committee of the International Red Cross Society, and the Association of Military Surgeons of the United States.

Of all these journals the *Archives de Médecine et de Pharmacie Militaires* of Paris is the oldest, having been in existence for ninety years and being itself the successor of a series of military medical periodicals dating back to the year 1767.

The *Deutsche militararztliche Zeitschrift* has almost reached the age of thirty-two years.

The Russian military medical journal, the *Boyennо Meditsinski Journal* of St. Petersburg, has been published continuously for eighty-one years.

Up to 1903 Great Britain possessed no military medical journal, but in that year the Royal Army Medical Corps inaugurated the publication of the *Journal of the Royal Army Medical Corps*. Japan has an up-to-date medical military journal, while the *Journal of the Association of Military Surgeons of the United States*, from the July issue of which we gather the facts mentioned, covers a broader field than that of any other country, as it combines in its clientele, the Medical Department of the Army, the Medical Corps of the Navy, the Public Health and Marine Hospital Service of the United States, and the Medical Departments of the National Guard, Militia and State Forces of the several commonwealths comprising the Union.

Cancer Research in Tropical Countries.

The inquiries into all that concerns cancer, which are being prosecuted in almost all the civilized countries of the world, have resulted thus far in no startling and definite discoveries as to the origin of malignant growths. Nevertheless, some progress has been made toward this end, and our knowledge of cancer generally is continually increasing. The assertion has often been made that cancer is extremely rare in tropical climates, and some observers have stated that the disease does not attack many native races of lands situated in the torrid zone. These statements may be true; and that there may be countries whose inhabitants are free from cancer is by no means unlikely, but until the question has been decided by exhaustive inquiry, it would be absurd to regard the matter as proven.

The *Journal of Tropical Medicine*, June 15, deals with this phase of the cancer problem editorially, and points out that it is imperative to gather information as to the presence or absence of malignant diseases in tropical countries if the present investigation of cancer is to attain scientific value. If a specific disease be absent from a country, there must be some reason for its absence, and if this reason can be traced to a purely local cause, then a valuable means of prevention may be at hand. Therefore, medical men who live in tropical countries, should be keenly on the lookout for all signs of malignant disease, even where no cases have been found. The solution of the cancer problem is one of the most difficult that has ever been placed before scientific men. To bring its investigation to a successful issue requires that advantage be taken of every opportunity to gain knowledge. Every point must be considered, and every detail in connection with cancer must be thoroughly probed in order finally to triumph in laying bare the unknown features of this disease.

Plea for Federal Control of Quarantine Regulations.

The Texas quarantine against Mexico, imposed last spring, and still existing in a modified form, has given rise to a considerable amount of dissatisfaction in Mexico. Of course it is not denied that the health authorities of Texas had every right to endeavor to protect their State against yellow fever, but the view is held by many that the measures adopted were altogether too sweeping. Indeed the fact has been recognized by the executive of Texas, the Governor, it is said, having served an order upon the health officer to recede from his position. At any rate the action of the Texas official has caused a certain amount of resentment on the part of the inhabitants of Mexico, and it is considered that it would be desirable to have our quarantine relations, at least when they concern foreign nations, in the hands of the Federal Government.

A special correspondent of the *Evening Post* in Mexico upholds such a course, and points out that an important reason for Federal regulation of international quarantine lies in the question of the validity of consular certificates. "In one sense," says the writer, "the Texas authorities are reasonable in refusing to accept them. The consuls of the United States in Mexico are officers only of the Federal Government, and the Texas authorities have no official relations with them, and no right to issue to them instructions with regard to what proofs they shall require before issuing certificates of health. Of course, a consul will ordinarily be willing to do anything reasonable in this regard, but it is entirely within his discretion as to what requirements he shall make before issuing certificates of this sort. On the other hand, if a quarantine is imposed by the Federal Government the State Department at once issues instructions to him as to proof of travelers' whereabouts, etc., with which he is sworn to comply faithfully."

Neuropathology and Internal Medicine.

The relation of nervous diseases to psychiatry and to internal medicine has hitherto been regarded as a subject of discussion for psychiatrists alone. It seems opportune, therefore, to consider the question

from the viewpoint of the general practitioner. Friedrich Schultze of Bonn contributes a most interesting discussion on this topic to the *Munchener medizinische Wochenschrift*, of July 19, 1904, in which he regards the subject from the standpoint of university instruction, the principal aim of which should be to develop physicians and not specialists. He fears that in many universities there has been a tendency to separate the field of internal medicine into a number of isolated studies, which in the course of time are gradually relegated to specialists, so that very little remains with which to carry on a clinic on what were formerly termed the "internal diseases." Thus we have departments in acute infectious diseases, pulmonary diseases, children's diseases, diseases of the digestive organs and metabolism, and numerous others, and nothing is left as material for the clinician who must educate the general practitioner, except perhaps bronchitis, pleuritis, or diseases of the suprarenal glands. But his special cause of complaint seems to be that now the psychiatrists have arrogated to themselves all forms of nervous diseases. It seems perfectly proper, perhaps, to assign the consideration of mental disturbances to this department, which is all that in reality it can be made to include, but this should not include the right to claim and treat every case of hysteria, epilepsy, or nervous lesion, and in this way to exclude them from other clinics. Schultze thinks they are as little justified in taking up this subject as the general surgeon would be in claiming every variety of arthritis for consideration and treatment by his methods.

The Pure Waters of the Drainage Canal.

The Illinois State Board of Health, in a recent report, summarizes the results of the investigations made to determine the sanitary effect of the new flow southward from Lake Michigan, through the Chicago drainage canal. The board holds that not only do the waters of the canal in no wise contaminate the water supply of towns along the Illinois and Missisippi rivers, but that the waters of those streams are actually rendered more potable by the added flow coming down from Chicago. Concerning the alleged contamination of the St. Louis water supply by Chicago sewage, the report asserts that it would be well for that city did it drink the Chicago water. St. Louis, it says, takes its water from a point on the west side of the Mississippi but a short distance below the mouth of the Missouri, so that the great bulk of the supply is taken from the Missouri river water. But the water of the Missouri river above its mouth shows evidence of more serious sewage contamination than does the water of the Illinois river above its mouth. A great part of the contamination of rivers comes from the drainage from farms and villages, the sewage from cities and refuse from manufacturing industries along their banks. In the case of the Illinois river, the water of the drainage canal actually improves that of the river by the dilution of this original contamination, and the same improvement would be effected in the Missouri water—the true source of St. Louis' supply—could it be diluted with the water of the drainage canal. All of which will be of great comfort to the citizens of St. Louis, if they will accept the argument and the statements upon which it is based.

A Village Quarantined.—The entire village of Dresden, N. Y., was placed under quarantine last week on account of an epidemic of varioloid, and nearly 500 inhabitants were isolated. The State Board of Health had charge of the quarantine.

News of the Week.

American Medical Editors' Association.—The thirty-fifth annual meeting of this association was held at Atlantic City, in connection with that of the American Medical Association, under the presidency of Dr. C. E. de M. Sajous. A number of papers were read and discussed; a resolution was adopted commending the editor of the *Ladies' Home Journal* for his action in publishing the alcoholic strength of many of the most popular patent medicines; a resolution of regret for the death of Dr. I. N. Love was passed; a committee was appointed to prepare a draft of a new constitution and by-laws to be presented at the next annual meeting, and twenty-eight new members were admitted. The following officers were elected: *President*, Harold N. Moyer, Chicago, Ill.; *Vice-Presidents*, C. Evelyn Pilcher, Carlisle, Pa., and O. F. Ball, St. Louis, Mo.; *Secretary* and *Treasurer*, J. MacDonald, Jr., New York; *Executive Committee*, C. E. de M. Sajous, chairman; John Punton, W. A. Young, W. C. Abbott, H. M. Simmons, C. F. Taylor, and Chas Wood Fassett. The association now numbers over one hundred members.

Sir Felix Semon, who is to deliver the address on Laryngology at the St. Louis Congress of Arts and Sciences, will arrive at New York early in September. He will be the guest, while in this city, of Dr. George M. Lefferts, and also of Dr. Emil Mayer, who is associated with Dr. Lefferts as co-editor of the *Internationales Centrablatt fur Laryngologie*, and of which Sir Felix has been editor in chief since its beginning twenty years ago. The American tour, which has been arranged by Dr. Mayer, will include stops at Niagara Falls, Chicago, St. Louis, Washington, Philadelphia, and Montreal, in each of which places Sir Felix and Lady Semon will be entertained by the leading laryngologists. In Canada Dr. Semon will take a four weeks' hunting trip, returning to New York City October 31 to remain a week before sailing for home. This last week will be a busy one, as the program includes a dinner under the auspices of the Laryngological Section of the New York Academy of Medicine, an address on Malignant Diseases of the Larynx at Hoosack Hall, by invitation of the same section, and receptions on different evenings to both Sir Felix and Lady Semon by Dr. Lefferts, Dr. Emil Mayer, and Dr. Thos. R. French of Brooklyn.

Directory of Institutions for the Care of the Tuberculous.—The National Association for the Study and Prevention of Tuberculosis, in coöperation with the Committee on the Prevention of Tuberculosis of the Charity Organization Society of New York City, is preparing a directory of the various agencies, existing and projected, in the United States and Canada which care for persons suffering from any form of tuberculosis or which work in any way for the restriction of the disease. This directory will include information in regard to hospitals, sanatoria, dispensaries, and camps especially designed for tuberculous patients or with especial provision for them, whether public or private; insane hospitals and prisons in which special provision is made for the tuberculous inmates; State commissions and private societies formed for the purpose of investigation or of diffusing information; and a summary of the efforts being made by the boards of health in the principal cities. A tentative list of institutions has been made which includes 102 sanatoria, 18 special clinics for the treatment of tuberculosis, and 12 insane hospitals and prisons with special provision for the treatment of tuberculous inmates. As it is desired to make this directory as complete and accurate as

possible, any additional addresses, or any reasons why institutions that are included should be omitted, will be welcomed. Communications should be addressed to the Committee on the Prevention of Tuberculosis, 105 East Twenty-second Street, New York City.

The Cook County, Ill., Institutions at Dunning.—Four of the buildings authorized by the people of Cook County when they approved the recent bond issue of $500,000 have been completed. They are, the Home for the Cure of Tuberculosis, which has taken the place of the old consumptive hospital, and three cottages for the treatment of insane persons. The Home for the Cure of Tuberculosis was built after a careful investigation along the newest lines for the treatment of the disease. The cottages for the insane represent the newest type of hospital treatment. They are large, sunny and airy, and are without prison-like bars on the outside of the windows. The living rooms are separate from the dormitories, and in all respects the cottages look and are conducted much like private residences. These three cottages are connected by an ornamental colonnade. They are of pleasing architecture, and they make an ornate head for the avenue of cottages at the Dunning Institutions. In addition to the three new cottages, the large farm cottage is now nearing completion. This is designed for patients who are able to work on the farms. It is supplied with all modern facilities, including shower baths, and offers facilities for the new treatment for the insane by providing employment for mind and body, instead of forcing the sufferers to remain idle. Still another building is now under erection, the foundation already being in, to provide adequate morgue facilities and room for the pathological laboratory and for clinical lectures. The lectures will be conducted in an amphitheater. The facilities afforded in this building will attract students of medicine, and will also cause experts in various diseases treated there to visit the institutions to lecture to doctors, internes and attendants, and in that way improve the medical service to the poor. Work has also been begun on the Children's Building at the County Hospital. This will be a large, roomy, fireproof structure, built on the most modern lines.

A New Ophthalmological Journal.—A new quarterly journal is announced to appear October 1, 1904, entitled *Ophthalmology*. It will be a periodical of about 250 pages, devoted to original essays, abstracts of original articles appearing in domestic and foreign literature, and book reviews. The following well-known ophthalmologists and editors are in charge of the various departments: Dr. H. V. Wurdemann of Milwaukee will be managing editor and publisher, and Dr. Nelson M. Black of Milwaukee, assistant editor. In charge of special departments will be: Drs. Chas. H. May, New York City; Casey A. Wood, Chicago; Chas. A. Oliver, Philadelphia; Blencowe E. Fryer, Kansas City; Albert B. Hale, Chicago; Edmond E. Blaauw, Buffalo; Chas. Zimmermann, Milwaukee; Dr. Wm. Zentmayer, Philadelphia; J. Guttman, New York City; Frank Allport, Chicago; M. Wicherkiewica, Cracow, Austria; Mitsiyasu Inouye, Tokio, Japan; Claud Worth, F.R.C.S., London, England.

Examiners of the State Board of Alienists.—At the session of the New York State Legislature last winter a law was passed creating a State Board of Alienists to act in concert with the United States examiners at the port of New York in the inspection and return to their own country of all immigrants suspected of insanity, epilepsy, or imbecility. Under this law Dr. Sidney D. Wilgus of Brooklyn has been appointed by the State Commission in Lunacy as chief examiner, at a salary of $5,000. The Lunacy Commission also appointed as assistant examiners and members of this board Dr. George D. Campbell and Dr. W. E. Sylvester of Manhattan, at a salary of $3,000 each.

Deaths in New York State During June.—The monthly bulletin of the State Department of Health reports 10,997 deaths in June, which is about 1,500 in excess of the average for the month during the past five years. The excess is, however, accounted for in great part by 1,362 deaths from accident in New York City, most of them occurring in the burning of the *Gen. Slocum*. There were 150 more deaths from tuberculosis than in the same month a year ago, and the number from pneumonia and other acute diseases of the respiratory organs was large, though not more than half as many as in May. Among epidemic diseases cerebrospinal fever was the only one showing an increase, the number of deaths from this disease during June being the same as in April.

Sir William Mitchell Banks, F.R.C.S., whose death on August 9 is announced by cable, was born in Edinburgh in 1842, and took his degree of M. D. at the university in that city. He was for a short time demonstrator of anatomy at the University of Glasgow, but in 1866 removed to Liverpool. Many in this country will remember meeting him in 1897 at Montreal, which city he visited in the summer of that year as chairman of the surgical section of the British Medical Association. He was knighted in 1899.

Cholera in St. Petersburg.—The woes of Russia are endless, and now it is reported that St. Petersburg is threatened with an epidemic of Asiatic cholera. The disease appeared some days ago, and thus far the number of deaths is believed not to have been great, though the authorities have not published any official figures.

Typhoid Fever in the Bronx.—Twenty-five cases of typhoid fever have been discovered in the colony of Italian laborers employed in constructing the Jerome Park reservoir. The source of the outbreak is not known.

Large Bequest to Tulane University.—The will of the late Alexander C. Hutchinson, who died in New Orleans December 7, 1902, provides for the payment of annuities to sisters of the testator during their life, and the residue of the estate is set aside for the medical department of Tulane University, Louisiana, after three bequests of $20,000 each are paid to New Orleans institutions. The appraisement shows the testator left a personal estate amounting to $1,020,000 and considerable real estate, the value of which is unknown.

Associated Meetings of the Northern New York Medical Association and the St. Lawrence County Medical Society.—It has been decided to hold the meeting of these two bodies on October 18, 1904, at Ogdensburg, N. Y., the Northern New York Medical Association holding session under the presidency of Dr. M. D. Briggs, during the afternoon, and the County Society, under the presidency of Dr. E. M. Somers, during the evening of the same day. The afternoon session will be held at the St. Lawrence State Hospital, upon the invitation of the Superintendent, Dr. R. H. Hutchings. The evening session will take place in the City Hall. Following the evening meeting a banquet will be held under charge of both societies. This arrangement will permit members of either society to attend both meetings, and it is hoped that the members will coöperate as far as possible to make the meeting both pleasant and profitable.

Enforcing the Illinois Pure Food Law.—State Commissioner Jones of Illinois has been unusually vigorous in prosecuting manufacturers of food products, and it is said that already suits have been brought against two hundred dealers and manufacturers for alleged violations of the pure food law. Many of the suits charge false labeling, while the bulk of them allege adulterations of the most injurious character. Among the adulterations found are artificial butter, impure maple syrup, and spurious vinegar. The belief is prevalent that Illinois affords a rich picking for dealers in and manufacturers of food frauds. That this belief is well-founded is shown by the fact that one hundred of these suits are against Cook County dealers, showing that the city with its two million consumers offers a market for food adulteration and misbranded food products so large as almost to defy the efforts of the most watchful and energetic food commissioner and food inspectors.

Dr. William T. Jenkins, ex-Health Officer of the Port of New York, has been appointed Sanitary Engineer in the Health Department at $2,400 a year. Dr. Jenkins was a coroner's physician for ten years until, in 1892, he was placed in charge of the New York quarantine station by Governor Flower. In the summer of that year cholera was epidemic in Hamburg, and the new health officer gained a name for himself by his active efforts to keep the disease out of this country.

Smallpox in Chicago.—Three patients with smallpox were sent to the Isolation Hospital during the week ended July 23, and a fourth one was found, who had recovered at home, without the nature of the disease being recognized by the attending physician. From this unrecognized case many exposures resulted, and some of the patients now in the hospital contracted the disease from this source. Three had never been vaccinated; one had a mark made in childhood, twenty-three years ago. One death occurred at the hospital during the week—that of an unvaccinated man twenty-six years old; his unvaccinated child, three months old, was in the hospital with smallpox, and his vaccinated wife was also in the hospital nursing the child.

More Filtered Water in Philadelphia.—The promise is made by the Chief of the Filtration Bureau that every part of West Philadelphia will be supplied with filtered water by the middle of August.

License Required to Dispense Liquors.—Complaint having been made that a number of druggists and physicians were dispensing liquor in contravention of the statutes, the Collector of Internal Revenue at Philadelphia has received instructions to the effect that a practising physician who, without holding the special tax stamp of a retail liquor dealer under the United States Internal Revenue laws, furnishes his patients with distilled spirits, wine, or malt liquors under conditions constituting sales of these liquors, directly or indirectly, involves himself in liability to criminal prosecution under these laws, unless he shows that the liquors thus furnished have been compounded into medicines by the addition of some drug or medicinal ingredient. If the liquors are not so compounded he cannot sell them even for medicinal purposes without involving himself in special tax liability.

Obituary Notes.—Dr. Romeo F. Chabert of Hoboken, N. J., died at Asbury Park on August 1, at the age of seventy-six years. He was born in London, but came to this country in early life and studied medicine here, receiving his degree from the New York University Medical School in 1856. He was a member of the New Jersey State Medical Society; founder and consulting surgeon of St. Mary's Hospital, Hoboken; consulting physician of the Bayonne Hospital, and for many years a member of the board of managers of the State Asylum at Morris Plains.

Dr. Robert Milbank of this city died of apoplexy at the home of a relative in Port Chester on August 4. He was born in 1838, and was graduated from the New York University Medical School in the class of 1878. He was a member of the New York Academy of Medicine, of the Medical Society of the County of New York, and of the Society of the Alumni of Bellevue Hospital.

Dr. Orlando Brown died at his home in Washington, Conn., on August 4, at the age of seventy-seven years. He was graduated from the Medical Department of Yale University in 1861, and at once entered the army as assistant surgeon of the Eighteenth Massachusetts Volunteers. He served throughout the war, in which he distinguished himself in hospital organization and management. In 1865 he was made colonel of a regiment of colored troops, and later retired with the rank of brigadier-general. He had practised medicine at Washington for many years, and was one of the most widely known physicians of Litchfield County. He was a member of the Connecticut State Medical Society.

Dr. A. Carter Webber died on August 5 at the home of his son, Dr. George A. Webber, at Manchester-by-the-Sea, Mass. Dr. Webber was born in Boston seventy-eight years ago, and was graduated from the Harvard Medical School in the class of 1849. He retired a few years ago, after having rounded out fifty years of active medical practice.

Dr. J. Converse Rising, a retired physician, formerly of this city, died at the home of his son in Greenwich, Conn., on August 3, at the age of eighty-six years. He was born in Suffield, Conn.

Dr. Francis F. Cassaday died in Philadelphia of cerebral hemorrhage on August 3, at the age of sixty-three years. He was graduated from Jefferson Medical College in the class of 1863.

Dr. O. W. Lounsbury of Wyoming, Ohio, was found dead in his stable on August 6. He had been suffering from an acute stomach trouble for several days, but had recovered sufficiently to be able to be about.

Dr. Ferdinand Hasbrouck, a well-known dentist of this city, died on Sunday after an illness of eight months from cancer of the stomach. He was seventy years old. Dr. Hasbrouck was one of the first to take up, thirty years ago, the use of nitrous oxide as an anæsthetic in the extraction of teeth. In the early days of "laughing gas," before it was thoroughly understood, patients came to Dr. Hasbrouck from all over the United States and from Europe. For years he lectured in the New York College of Dentistry on nitrous oxide gas. His son, Dr. James F. Hasbrouck of New York, and a daughter survive him.

Dr. Charles Newton Thompson of this city died at Nantucket, Mass., on August 7, after a lingering illness. He was born in Somersworth, N. H., on March 6, 1850, and was graduated from the Bellevue Hospital Medical School in 1884. He was for many years surgeon of the Ninth Infantry, N. G. S. N. Y.

Dr. Albert W. Warden of Union Hill, N. J. died on August 9 at the Presbyterian Hospital of septicæmia. Three weeks ago, while performing a slight operation, he scratched his hand, and in a few days signs of infection appeared. Amputation was advised but he would not consent, being confident of ultimate recovery. He was a graduate of the New York University Medical School in the class of 1880, and was a member of the New Jersey State Medical Society.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

THE QUEEN AT HOSPITALS—THE KING'S HOSPITAL FOR OFFICERS—THE WIGHTMAN LECTURE—THE OPHTHALMOLOGICAL SOCIETY AND THE SPECTACLE-MAKERS' COMPANY—HOSPITAL FOR GENTLEWOMEN—PRIZES AT BART'S.

LONDON, July 22, 1904.

On Saturday the Queen, accompanied by Princess Victoria, paid a visit to the Hospital and Home for Incurables. Her Majesty was conducted over the institution by Dr. Scamra and spoke a few words to each of the patients, eighty in number, and gave each a bunch of flowers from the gardens of Buckingham Palace. Her Majesty has sent £50 to the East End Horticultural Society which she visited last week, as I told you, and which gives surplus receipts to the London Hospital. Her Majesty has also sent £25 for the poor of the parish of St. George's in the East, the flower show of which she visited on her way to the Horticultural Society. This afternoon the Queen distributed certificates to members of the Royal Pension Fund for Nurses, of whom 2,000 were entitled to attend, but many were engaged on cases and could not come. Nevertheless this is the largest review of nurses ever held by Her Majesty, who has taken keen interest in the Fund from its foundation.

King Edward VII's Hospital for Officers will not be wanting for medical and surgical aid, for the Prince of Wales, president, and the Duke of Connaught, vice-president, have appointed for a period of five years a staff of two dozen eminent physicians and surgeons and two consultants.

Heredity has been for some time rather at a discount as a cause of disease. The discovery of the tubercle bacillus gave a shock to the holders of the theory of hereditary disease, and the advance since in our knowledge of parasitic disease has gone far to eliminate notions once considered axioms. Mr. Clement Lucas has taken a more moderate view if he has not in some degree endeavored to rehabilitate the hereditary theory. Last week he delivered the Wightman Lecture before one of our youngest societies, the "Society for the Study of Disease in Children," established about four years ago. His subject was "Hereditary Bias and Early Environment in Relation to the Diseases and Defects of Children." After some general remarks he admitted as a truth that the child must resemble its parents, and said the variations in the appearance of offspring are often due to the relative vigor of the parents. He went on to state that when he first became connected with a children's hospital he inquired into the family history of every tuberculous patient and found that in nearly every case one or other parent had suffered from phthisis. Can we then throw over altogether diathesis as a factor? The so-called types of consumption may rather be considered as an effect of heredity than a cause. If Cohnheim's theory be true, that the bacilli can penetrate the germ or sperm cells, the outlook of the offspring of consumptives is hopeless from the earliest period. Up to the time of Hansen's discovery of the bacillus lepræ (1871), the hereditary nature of leprosy was generally believed in, and even now it is held in some places, though the Indian Commission failed to find any evidence of heredity in more than 5 or 6 per cent. of the cases. Syphilis, we know, descends from parent to offspring but very seldom affects the third generation. Neither Mr. Hutchinson nor the lecturer had met with more than one doubtful instance of transmission to the third generation. If both parents are syphilitic the result to the offspring is doubly disastrous. The later children of syphilitics are less affected than the earlier.

Rickets, so common in large cities, is responsible for much of the degeneration of which we hear so much, but it is purely a dietetic disease and may be induced in any child by bad feeding. Rheumatism can no longer be regarded as purely hereditary, as the diplococcus has been discovered. The antithetic counterpart, gout, can be induced in successive generations. The children of gouty parents are likely to be brought up under the conditions in which the parents live. It is probable that this disease may be found to be of an infective nature. Dr. Shuttleworth found in 20 per cent. of cases of idiocy a history of mental disease in one or other parent. Other researches show that certain neuroses are transmitted in definite proportions to sons and daughters. Both psychical tendencies and physical qualities are, in fact, transmissible. Hæmophilia is peculiar, as it selects the males and is transmitted by the females. Other abnormal conditions appear to follow the same rule. Coloboma, nyctalopia, and other ocular defects are distinctly hereditary. It is in external defects that heredity is most marked. Ichthyosis is seen in several members of a family for several generations. Psoriasis similarly runs in families. Supernumerary digits have been observed through five generations. With regard to hare-lip, the lecturer has previously recorded the fact that absence of the lateral incisor tooth in the mother is frequently the precursor of this deformity in her offspring, and on this occasion he announced further that a feebly developed incisor may foreshadow hare-lip.

The occurrence of intrauterine amputations has been attributed to constriction by the cord, but there are many arguments against such a view. Mr. Lucas suggested that such deformities are due to errors far back in the process of development. The influence of the parents upon the physical deterioration of the present day was declared by the lecturer to be more important than the effects of bad food and surroundings upon the children.

The Ophthalmological Society has at length woke up to its responsibility and has issued a report on sight-testing by spectacle-makers. For some time a member of that society was an examiner for the Diploma of the Worshipful Company of Spectacle-makers—a city guild with no authority whatever to issue such documents. That gentleman has only lately resigned the honorable (?) office of examiner to the trade guilds' attempt to palm off its members as qualified to advise the public. It is to be hoped no other member will accept the position or that anyone who does will be expelled from the society which has at last given a warning signed by the president—Mr. John Tweedy—that "it would be misleading and dangerous to the public to countenance any proposal to certify as competent to advise and prescribe for defects of vision any one who has not had an efficient medical and surgical training." It is obvious that a company of mechanics ought, in the interests of the public, to be prevented from issuing to other mechanics certificates which will lead to the belief among the less enlightened that the holder is competent to advise on diseases. But quackery here is so rampant, the protection of the profession so absent, and the public so ready to follow any pretender, that only mere protests like the Ophthalmological Society's can be employed against the encroachments which are a disgrace to our law. This protest mentions that spectacles may in some cases destroy the sight or put the life of the patient in danger. But what is that to a legislature which fears to forfeit the votes of those engaged in such dangerous doings?

Lord Lister, Sir Thomas Barlow, Sir Wm. Church, and others have joined in an appeal on behalf of the Hospital for Invalid Gentlewomen. The object of the institution is to give ladies of small means a home where medical and surgical treatment can be carried out at a minimum cost. The payments to be made range from 25s. to 50s. a week and a few patients are admitted free. The ordinary expenditure exceeds the income by £500. The home is to be shortly removed to a new site and £4,000 will be needed for equipments and removal.

The Bishop of London distributed the prizes at St. Bartholomew's Hospital, and took occasion to say the clerical and medical professions should work harmoniously. True enough, but the bishop should instruct the lower clergy in the same sense and reprove their continual advocacy of quackery.

OUR VIENNA LETTER.

(From Our Special Correspondent.)

ABSORPTION OF LIME IN RACHITIS—ACUPUNCTURE—ETHYLCHLORIDE SPRAY FOR X-RAY BURNS—ANGIOMA RACEMOSUM OF THE NOSE—A LUNG SEQUESTRUM—INJURY OF THE TRANSVERSE SINUS—INHALATION OF TUBERCULIN—NEW VIENNA HOSPITAL.

VIENNA, July 10, 1904.

Dr. M. PFAUNDLER spoke as guest at a recent meeting of the Vienna Pediatric Society, on the absorption of lime in rachitis, a field in which he has worked successfully for several years. He said that the most certain sign of rachitis is the softness of the bones, which, if burned, give almost no ash. Especially are the lime and phosphoric acid diminished. Bone and cartilage of healthy individuals possess the specific power of depositing lime salts within themselves, and his power in rachitic individuals appears to be reduced. According to some authors, the chief place for the deposition of lime is the immediate neighborhood of the cells, and, according to others, the cells themselves. The component parts of the bone salts are derived from the blood, but it is not entirely clear in what form the salts circulate in the blood, nor yet whether the salt is deposited from solution or in the form of very fine granules. The chemical constitution of bone substance is almost the same among all vertebrate animals, and the relative proportions are not changed in pathological conditions. A peculiar change precedes the calcification of the cartilage and of the bony tissue, metaplasia, which goes along with a higher grade of basophilia. The changed tissue has the property of depositing in itself metal salts and color substance, and is even described as a true cell degeneration. The speaker

had placed dead and living tissues in a solution of gelatin with calcium chloride and asserted that they took the calcium out of the solution. This was especially noticeable in the bones of dogs which by special feeding had been deprived of more or less calcium. In rachitis the molecular taking in of calcium appears to be disturbed. The cause of this must lie in the bone substance—that is, the receivers of the calcium salts appear to have suffered change.

A very interesting address was delivered before the Society for Psychology and Neurology in Vienna by Dr. E. Okada of Tokio. He spoke, and at the same time gave a demonstration of "hari," acupuncture, and "kju," the moxa, as employed in Japan. Okada gave, first, an historical survey of the treatment, in which he called attention to the fact that it had been used 1350 years ago in an institution, but was first well developed about 300 years ago. He showed different types of the common and the so-called pressure moxa, which is burned over the determined places of the skin (called "points" or "holes") and then extinguished. For acupuncture, Okada showed a gold and a silver needle, and compared the effects and method of working, together with the moxa. As indications for their use he enumerated neuralgia, cramps, paralysis, stomach, and intestinal diseases, etc. In conclusion, Okada gave a review of the topographical relations of the so-called "points" and "holes," and also of this particular treatment.

Professor Riehl showed a girl with cicatricial atrophy of the skin of the lower half of the face, and numerous telangiectases in the same place, and also on the neck, the anterior part of the breast, and extending down to the epigastric region. The cause was *x*-ray treatment, which had been used for hypertrichosis. Stiff hairs could still be seen, especially on the chin. The treatment was conducted with imperfect protection, each separate place receiving the rays about seven times, and was followed in the now atrophied part by an intense reaction. Riehl showed the patient, for the reason that one of the therapeutic measures employed for counteracting the disfiguring redness appeared to be successful. Scarification was of no avail. Electrolytic treatment had been used in two places and had yielded, up to the present time, but slightly satisfactory results. On the other hand, two other red spots upon which, the one for one minute, the other on two different days for one minute each time, ethyl-chloride spray had been applied until the part was white, appeared now decidedly whiter than the surrounding skin, and in both, the vessel ramifications had nearly disappeared. The portions of skin experimentally and cautiously treated with cold, on the next day were somewhat swollen and tender on pressure, and desquamated after about three days.
